# Table of Contents

## **Preface**

xiv

## **ECAL - General Track**

Simon Tudge, Richard Watson and Markus Brede. <i>Cooperation and the Division of Labour</i>	1
Yutetsu Kuruma, Hideaki Matsubayashi and Takuya Ueda. <i>Autonomous construction of synthetic cell membrane</i>	9
Jared Moore, Anne Gutmann, Craig McGowan and Philip McKinley. <i>Exploring the Role of the Tail in Bipedal Hopping through Computational Evolution</i>	11
Kiril Kiryazov and Robert Lowe. <i>The role of arousal in embodying the cueXdeficit model in multi-resource human-robot interaction</i>	19
Simon Alderton and Jason Noble. <i>Simulating Sleeping Sickness: a two host agent-based model</i>	27
Adam Erskine and J. Michael Herrmann. <i>Cell Division Behaviour in a Heterogeneous Swarm Environment</i>	35
Guillaume Beslon, B��r��nice Batut, David P. Parsons, Dominique Schneider and Carole Knibbe. <i>An alife game to teach evolution of antibiotic resistance</i>	43
Eduardo J. Izquierdo, Miguel Aguilera and Randall D. Beer. <i>Analysis of Ultrastability in Small Dynamical Recurrent Neural Networks</i>	51
Dov Pechenick, Jason Moore and Joshua Payne. <i>The influence of assortativity on the robustness and evolvability of gene regulatory networks upon gene birth</i>	59
Flavio L. Pinheiro, V��tor V. Vasconcelos, Francisco C. Santos and Jorge M. Pacheco. <i>Self-organized game dynamics in complex networks</i>	61
Stefano Nichele and Gunnart Tufte. <i>Evolution of Incremental Complex Behavior on Cellular Machines</i>	63
Simon Hickinbotham, Michael Weeks and James Austin. <i>The ALife Zoo: cross-browser, platform-agnostic hosting of Artificial Life simulations</i>	71
Micah Rosenkind, David Arnold and Graham Winstanley. <i>A Temporal Pattern Predictor for Virtual Characters</i>	79

Lance Williams. <i>Evolution of Tail-Call Optimization in a Population of Self-Hosting Compilers</i>	86
Qinxin Pan, Ting Hu, Angeline Andrew, Margaret Karagas and Jason Moore. <i>Bladder cancer specific pathway interaction networks</i>	94
Roman Miletitch, Vito Trianni, Alexandre Campo and Marco Dorigo. <i>Information Aggregation Mechanisms in Social Odometry</i>	102
Jie Tan, Jason Moore and Ryan Urbanowicz. <i>Rapid Rule Compaction Strategies for Global Knowledge Discovery in a Supervised Learning Classifier System</i>	110
Christoph Salge, Cornelius Glackin and Daniel Polani. <i>Empowerment and State-dependent Noise - An Intrinsic Motivation for Avoiding Unpredictable Agents</i>	118
Randal Olson, Masoud Mirmomeni, Tim Brom, Eric Brugger, Arend Hintze, David Knoester and Christoph Adami. <i>Evolved digital ecosystems: Dynamic steady state, not optimal fixed point</i>	126
Omer Markovitch and Doron Lancet. <i>Prebiotic Evolution of Molecular Assemblies: From Molecules to Ecology</i>	134
Veljko Potkonjak, Vladimir M. Petrovic, Kosta Jovanovic and Dragan Kostic. <i>Human-Robot Analogy - How Physiology Shapes Human and Robot Motion</i>	136
Alessandro Fontana and Borys Wrobel. <i>An artificial lizard regrows its tail (and more): regeneration of 3-dimensional structures with hundreds of thousands of artificial cells</i>	144
Lenka Pitonakova and Seth Bullock. <i>Controlling Ant-Based Construction</i>	151
Markus Brede and Jason Noble. <i>The coevolution of costly heterogeneities and cooperation in the prisoner's dilemma game</i>	159
Miguel Gonzalez, Richard Watson, Jason Noble and Patrick Doncaster. <i>Multiple Life-History Stage Competition and its Effect on Coexistence</i>	167
Taichi Haruna. <i>Robustness and Directed Structures in Ecological Flow Networks</i>	175
Vitor V. Vasconcelos, Flavio L. Pinheiro, Francisco C. Santos and Jorge M. Pacheco. <i>Bootstrapping back the climate with self-organization</i>	182
Benjamin Inden and Jürgen Jost. <i>Neural agents can evolve to reproduce sequences of arbitrary length</i>	184
Pierre Buesser and Marco Tomassini. <i>Spatial Organisation of Cooperation with Contingent Agent Migration</i>	192
Dusan Misevic, Antoine Frenoy and François Taddei. <i>In silico evolution of transferable genetic elements</i>	200
Daiki Komatsu, Kei Fujiwara and Shin-Ichiro M. Nomura. <i>Construction of a remote-controlled supramolecular micro-crawler</i>	208

Declan Baugh and Barry McMullin. <i>Evolution of G-P mapping in a von Neumann Self-reproducer within Tierra</i>	210
Paul Szerlip and Kenneth Stanley. <i>Indirectly Encoded Sodarace for Artificial Life</i>	218
Alberto Antonioni, Mattia Egloff and Marco Tomassini. <i>An Energy-Based Model for Spatial Social Networks</i>	226
Arash Khabbaz Saberi, Jan Friso Groote and Sarmen Keshishzadeh. <i>Analysis of Path Planning Algorithms: a Formal Verification-based Approach</i>	232
Nathaniel Virgo and Takashi Ikegami. <i>Autocatalysis Before Enzymes: The Emergence of Prebiotic Chain Reactions</i>	240
Matthew Egbert, Gerd Gruenert, Gabi Escuela and Peter Dittrich. <i>Synthetic signalling protocell networks as models of neural computation</i>	248
Tadao Maekawa, Manabu Honda, Norie Kawai, Emi Nishina, Osamu Ueno and Tsutomu Oohashi. <i>Heterogeneity and complexity of a simulated terrestrial environment account for the superiority of the altruistic gene</i>	250
Maja Murnik, Špela Petric and Miha Turšič. <i>Beyond Life Cycles</i>	258
Jean-Marc Montanier and Nicolas Bredeche. <i>Evolution of Altruism and Spatial Dispersion: an Artificial Evolutionary Ecology Approach</i>	260
Paul Williams and Randall Beer. <i>Environmental Feedback Drives Multiple Behaviors from the Same Neural Circuit</i>	268
Zoe Bukovac, Alan Dorin and Adrian Dyer. <i>A-Bees See: A Simulation to Assess Social Bee Visual Attention During Complex Search Tasks</i>	276
Atanas Radenski. <i>Using MapReduce Streaming for Distributed Life Simulation on the Cloud</i>	284
Kai Olav Ellefsen. <i>Balancing the Costs and Benefits of Learning Ability</i>	292
Markus Brede and Simon Tudge. <i>Replication strategies and the evolution of cooperation by exploitation</i>	300
James Snowdon and Ben Waterson. <i>When congestion can be useful: modelling driver diversion behaviour in road traffic networks</i>	308
Tomonori Hasegawa and Barry McMullin. <i>Exploring the Point-mutation Space of a von Neumann Self-reproducer within the Avida World</i>	316
Hiroki Mori, Yuzi Okuyama and Minoru Asada. <i>Emergence of diverse behaviors from interactions between nonlinear oscillator complex networks and a musculoskeletal system</i>	324

Dharani Punithan and Bob McKay. <i>Collective Dynamics and Homeostatic Emergence in Complex Adaptive Ecosystem</i>	332
Christian Darabos, Craig O. Mackenzien, Marco Tomassini, Mario Giacobini and Jason H. Moore. <i>Cellular Automata Coevolution of Update Functions and Topologies: A Tradeoff between Accuracy and Speed</i>	340
Christian Darabos, Britney E. Graham, Ting Hu and Jason H. Moore. <i>Bipartite Networks Show the Genotype-to-Phenotype Relationship in Biological Systems Models: A Study of the Robustness, Evolvability, and Accessibility in Linear Cellular Automata</i>	348
Adam Jackson and Richard Watson. <i>The Effects of Assortment on Population Structuring Traits on the Evolution of Cooperation</i>	356
Dov Pechenick, Joshua Payne and Jason Moore. <i>An alternative route to robustness: The relationship between assortativity, in-components, and characteristic path length in gene regulatory networks</i>	364
Marco Villani, Alessandro Filisetti, Stefano Benedettini, Andrea Roli, David Avra Lane and Roberto Serra. <i>The detection of intermediate-level emergent structures and patterns</i>	372
Elio Tuci, Boris Mitavskiy and Gianpiero Francesca. <i>On the evolution of self-organised role-allocation and role-switching behaviour in swarm robotics: a case study</i>	379
James Dyke and Iain Weaver. <i>Tipping points in Complex Coupled Life-Environment Systems</i>	387
Miguel Aguilera, Ignacio Morer, Xabier E. Barandiaran and Manuel G. Bedia. <i>Quantifying Political Self-Organization in Social Media. Fractal patterns in the Spanish 15M movement on Twitter</i>	395
Orly Stettiner. <i>Biology of Digital Organisms: How Language and tools Constructs Reality</i>	403
Kai Olav Ellefsen. <i>Evolved Sensitive Periods in Learning</i>	409
Jean Sirmai. <i>Autopoiesis Facilitates Self-Reproduction</i>	417
Solvi F. Arnold, Reiji Suzuki and Takaya Arita. <i>Evolution of Social Representation in Neural Networks</i>	425
Radek Hrbacek and Michaela Sikulova. <i>Coevolutionary Cartesian Genetic Programming in FPGA</i>	431
Takashi Ito, Marcin Pilat, Reiji Suzuki and Takaya Arita. <i>Coevolutionary Dynamics Caused by Asymmetries in Predator-Prey and Morphology-Behavior Relationships</i>	439
John Maher. <i>The Influence of Cell Type on Artificial Development</i>	446
Michal Joachimczak, Taras Kowaliw, Rene Doursat and Borys Wrobel. <i>Controlling development and chemotaxis of soft-bodied multicellular animats with the same gene regulatory network</i>	454
Bijan Ranjbar-Sahraei, Katerina Stankova, Karl Tuyls and Gerhard Weiss. <i>Stackelberg-based Coverage Approach in Nonconvex Environments</i>	462

Takahiro Sasaki. <i>Simulating Limited Diversity in Evolution of Influenza</i>	470
Timothy Moran, Markus Brede, Antonella Ianni and Jason Noble. <i>The Origin of Money: An Agent-Based Model</i>	472
Philippe Collard. <i>Beyond the schelling's segregation: is it equivalent to be repulsed by dissimilar rather to be attracted by similar?</i>	480
Shin-Ichiro M. Nomura, Yusuke Sato and Kei Fujiwara. <i>Molecular robotics approach for constructing an artificial cell model</i>	488
Hisashi Murakami and Yukio Gunji. <i>Lévy-like Distribution Shown by Intermittent Search Model with Misunderstanding Switch Pattern</i>	492
Mizuki Oka, Takashi Ikegami, Alex Woodward, Yiqing Zhu and Kazuhiko Kato. <i>Cooperation, Congestion and Chaos in Concurrent Computation</i>	498
John Lones and Lola Cañamero. <i>Epigenetic adaptation in action selection environments with temporal dynamics</i>	505
James Thorniley and Phil Husbands. <i>Hidden information transfer in an autonomous swinging robot</i>	513
Amber Ferger, Wai Fai Lau, Philipp Ross, Wyman Zhao, Hiroki Sayama and Steen Rasmussen. <i>Impact of Personal Fabrication Technology on Social Structure and Wealth Distribution: An Agent-Based Simulation Study</i>	521
Carlos Fernandes, Juan Laredo, Juan Julian Merelo, Carlos Cotta and Agostinho Rosa. <i>Adapting the Bak-Sneppen Model to a Dynamic and Partially Connected Grid of Hierarchical Species</i>	523
Joachim Erdei, Michal Joachimczak and Borys Wrobel. <i>Evolving gene regulatory networks controlling foraging strategies of prey and predators in an artificial ecosystem</i>	531
Gianluca Massera, Tomassino Ferrauto, Onofrio Gigliotta and Stefano Nolfi. <i>FARSA : An Open Software Tool for Embodied Cognitive Science</i>	538
Minami Takato, Shinpei Yamasaki, Shiho Takahama, Junichi Tanida, Ken Saito and Fumio Uchikoba. <i>Insect Type MEMS Micro Robot Controlled by CMOS IC of Hardware Neural Networks</i>	546
Tiago Baptista and Ernesto Costa. <i>Open-Ended Evolution of a Circadian Rhythm</i>	554
Ezequiel Di Mario, Iñaki Navarro and Alcherio Martinoli. <i>The Effect of the Environment in the Synthesis of Robotic Controllers: A Case Study in Multi-Robot Obstacle Avoidance using Distributed Particle Swarm Optimization</i>	561
Martin Stehlik, Adam Saleh, Andriy Stetsko and Vashek Matyas. <i>Multi-Objective Optimization of Intrusion Detection Systems for Wireless Sensor Networks</i>	569

Yuri Lenon Barbosa Nogueira, Carlos Eduardo Fisch de Brito, Creto Augusto Vidal and Joaquim Bento Cavalcante Neto. <i>Evolving Plastic Neuromodulated Networks for Behavior Emergence of Autonomous Virtual Characters</i>	577
Andrea Guarneri, Dario Maggiorini, Laura Anna Ripamonti and Marco Trubian. <i>GOLEM: Generator Of Life Embedded into MMOs</i>	585
Darius Falahat, Enrico Gerding and Markus Brede. <i>Evolving Behaviour-Dependent Strategies in Agent Negotiations</i>	593
Ralf Der and Georg Martius. <i>Behavior as broken symmetry in embodied self-organizing robots</i>	601
Payam Zahadat, Karl Crailsheim and Thomas Schmickl. <i>Social Inhibition Manages Division of Labour in Artificial Swarm Systems</i>	609
Tsubasa Azumagakito, Reiji Suzuki and Takaya Arita. <i>Cyclic Behavior in Gene-Culture Coevolution Mediated by Phenotypic Plasticity in Language</i>	617
Vasthi Alonso Chavez, James G. Dyke and C. Patrick Doncaster. <i>Detecting regime shifts in artificial ecosystems</i>	625
Sue Attwood, Lola Cañamero and Rene Te Boekhorst. <i>SimianWorld - A Study of Social Organisation Using an Artificial Life Model</i>	633
Simón C. Smith and J. Michael Herrmann. <i>Self-Organisation of Generic Policies in Reinforcement Learning</i>	641
António Homem Ferreira and Carlos Martinho. <i>ASAP: an Ant resource Search Algorithm for swarm-like P2P networks</i>	649
Anna Shcherbacheva and Tuomo Kauranne. <i>Swarm dynamics with limited perception - how do mosquitoes recognize a friend?</i>	657
Zbigniew Pliszka and Olgierd Unold. <i>Some Remarks on Dynamics of Binary Chromosomes Population</i>	663
Manuel Heras-Escribano, Jason Noble and Manuel De Pinedo. <i>The only wrong cell is the dead one: On the enactive approach to normativity</i>	665
Evert Haasdijk and Nicolas Bredeche. <i>Controlling Task Distribution in MONEE</i>	671
Francesco Pugliese and Davide Marocco. <i>The relationship between Flocking Behavior and the Emergence of Leadership</i>	679
Brian Hrolenok and Tucker Balch. <i>Learning Schooling Behavior from Observation</i>	686
Hiroataka Osawa and Michita Imai. <i>Evolution of Mutual Trust Protocol in Human-based Multi-Agent Simulation</i>	692

Julien Hubert, Eiko Matsuda and Takashi Ikegami. <i>Hebbian Learning In A Multimodal Environment</i>	698
Dario Maggiorini, Laura Anna Ripamonti and Samuele Panzeri. <i>Follow the Leader: a Scalable Approach for Realistic Group Behavior of Roaming NPCs in MMO Games</i>	706
Tomohiro Harada and Keiki Takadama. <i>Analyzing Program Evolution in Genetic Programming using Asynchronous Evaluation</i>	713
Payam Zahadat, Thomas Schmickl and Karl Crailsheim. <i>Evolution of Spatial Pattern Formation by Autonomous Bio-Inspired Cellular Controllers</i>	721
Takayuki Niizato. <i>Multiplicity of Interpretation in an Asynchronous Updating Rule: Emergence of Collective Cognition</i>	729
Yara Khaluf and Franz Rammig. <i>Task Allocation Strategy for Time-Constrained Tasks in Robots Swarms</i>	737
Margareta Segerståhl. <i>Formal Model of Living Systems</i>	745
Yuri Lenon Barbosa Nogueira, Carlos Eduardo Fisch de Brito, Creto Augusto Vidal and Joaquim Bento Cavalcante Neto. <i>Emergence of Autonomous Behaviors of Virtual Characters through Simulated Reproduction</i>	750
Takeo Kato, Koichiro Sato and Yoshiyuki Matsuoka. <i>Robust Optimization of Adjustable Control Factors Using Particle Swarm Optimization</i>	758
Paolo Arena, Luca Patanè and Roland Strauss. <i>The insect Mushroom Bodies: a paradigm of neural reuse</i>	765
Alessandro Di Nuovo, Davide Marocco, Santo Di Nuovo and Angelo Cangelosi. <i>Ballistic Action Planning in Robotics by means of Artificial Imagery</i>	773
Sjriek Alers, Bijan Ranjbar-Sahraei, Stefan May, Karl Tuyls and Gerhard Weiss. <i>Evaluation of an Experimental Framework for Exploiting Vision in Swarm Robotics</i>	775
Lorenzo Garattoni, Andrea Roli, Matteo Amaducci, Carlo Pinciroli and Mauro Birattari. <i>Boolean network robotics as an intermediate step in the synthesis of finite state machines for robot control</i>	783
Adrien Padirac, Alexandre Baccouche, Teruo Fujii, Andre Estevez-Torres and Yannick Rondelez. <i>Predator prey molecular landscapes</i>	791
Alessandro Filisetti, Alex Graudenzi, Chiara Damiani, Marco Villani and Roberto Serra. <i>The role of backward reactions in a stochastic model of catalytic reaction networks</i>	793
Vincent Ducharme, Richard Egli and Sylvie Jetté. <i>A cardiopulmonary system for a virtual patient</i>	802
Yukio Gunji, Tomoko Sakiyama, Sohei Wakisaka, Naotaka Fujii and Tomoaki Nakamura. <i>Artificial Causal Space-Time</i>	810

Jitka Cejkova, Damian Gorny, Petra Haufova and František Štěpánek. <i>“Artificial spores” - hybrid alginate microcapsules with encapsulated yeast cells</i>	818
Hideaki Matsubayashi, Yutetsu Kuruma and Takuya Ueda. <i>In vitro Synthesis of Membrane Protein Machinery toward the Construction of Artificial Cell</i>	824
Jerzy Maselko, James Pantaleone and Vitaliy Kaminker. <i>Experimental studied on growing chemical organisms</i>	825

### **Adaptive Hardware & Systems and Bioelectronics**

Julio G. Arriaga, George Kossan, Martin L. Cody, Edgar E. Vallejo and Charles E. Taylor. <i>Acoustic sensor arrays for understanding bird communication. Identifying Cassin’s Vireos using SVMs and HMMs</i>	827
--	-----

### **Adaptive Living Material Technologies & Biomimetic Microsystems**

Henderson Cleaves and Neil Anthony. <i>Prebiotic Organic Microstructures as Model Protocells</i>	829
--	-----

### **Artificial Immune, Neural and Endocrine Systems**

Ronald Thenius, Payam Zahadat and Thomas Schmickl. <i>EMANN - a model of emotions in an artificial neural network</i>	830
Stein Keijzers, Peter Maandag, Elena Marchiori and Ida Sprinkhuizen-Kuyper. <i>Image Similarity Search using a Negative Selection Algorithm</i>	838

### **Artificial Immune Systems - ICARIS**

Huikeng Lau, Iain Bate and Jon Timmis. <i>Immune-Inspired Error Detection for Multiple Faulty Robots in Swarm Robotics</i>	846
Grazziela Figueredo, Peer-Olaf Siebers, Douglas Augusto, Helio Barbosa and Uwe Aickelin. <i>The use of Agent-based Simulation to Discover Extreme Cases in Immune-Interactions with Early-Stage Cancer Scenarios</i>	854
Kevin Sim, Emma Hart and Ben Paechter. <i>Learning to Solve Bin Packing Problems with an Immune Inspired Hyper-heuristic</i>	856
Nicola Capodieci, Emma Hart and Giacomo Cabri. <i>An immune network approach for self-adaptive ensembles of autonomic components: a case study in swarm robotics</i>	864
Wilburn W. P. Tsang and Henry Y. K. Lau. <i>An Artificial Immune System-based Many-Objective Optimization Algorithm with Network Activation Scheme</i>	872
Mark Read, Magnus Tripp, Hannah Leonova, Louis Rose and Jon Timmis. <i>Automated calibration of agent-based immunological simulations</i>	874

Shangce Gao, Tao Gong, Weiya Zhong, Fang Wang and Beibei Chen. <i>Enhancing the learning capacity of immunological algorithms: a comprehensive study of learning operators</i>	876
Dongdong Zhao and Wenjian Luo. <i>Real-Valued Negative Databases</i>	884
Emma Hart, Mark Read, Chris McEwan, Uwe Aickelin and Julie Greensmith. <i>On the Role of the AIS Practitioner</i>	891
Paul Taylor, Fiona Polack and Jon Timmis. <i>Accelerating Immunos 99</i>	893
Henry Lau and Nicole Lee. <i>Modelling the migration and maturation of dendritic cells for automatic optimization of complex engineering problems</i>	899
Lingli Yu, Binglu Wu and Tao Gong. <i>A hierarchical support vector machine based on feature-driven method for speech emotion recognition</i>	901

### **Bioinspired Learning and Optimization**

Ana L. C. Bazzan. <i>Comparing Reinforcement Learning and Evolutionary Based Adaptation in Population Games</i>	909
Paulo Urbano and Loukas Georgiou. <i>Improving Grammatical Evolution in Santa Fe Trail using Novelty Search</i>	917
Matthew Crossley, Andy Nisbet and Martyn Amos. <i>Quantifying the Impact of Parameter Tuning on Nature-Inspired Algorithms</i>	925
Arnaud Zinflou, Caroline Gagne and Marc Gravel. <i>A hybrid genetic/immune strategy to tackle the multi-objective quadratic assignment problem</i>	933
Ariadne Costa, Patrícia Vargas and Renato Tinós. <i>Using explicit averaging fitness for studying the behaviour of rats in a maze</i>	940

### **Bioinspired Robotics**

Heiko Hamann. <i>Speciation Dynamics: Generating Selective Pressure Towards Diversity</i>	947
Shuhei Miyashita and Daniela Rus. <i>Multi-crease Self-folding by Uniform Heating</i>	955
Claire E. Gerrard, John McCall, George Coghill and Christopher Macleod. <i>Artificial Reaction Network Agents</i>	957
Mark Khazanov, Ben Humphreys, William Keat and John Rieffel. <i>Exploiting Dynamical Complexity in a Physical Tensegrity Robot to Achieve Locomotion</i>	965
Adam Stanton and Alastair Channon. <i>Heterogeneous complexification strategies robustly outperform homogeneous strategies for incremental evolution</i>	973

Gregory Vorobyev, Andrew Vardy and Wolfgang Banzhaf. <i>Conformity and Nonconformity in Collective Robotics: A Case Study</i>	981
Xiaofeng Xiong, Florentin Woergoetter and Poramate Manoonpong. <i>A Neuromechanical Controller of a Hexapod Robot for Walking on Sponge, Gravel and Snow Surfaces</i>	989
Fabien Hervouet and Eric Bourreau. <i>FIMO: Framework for Intrinsic Motivation</i>	997
Filippo Vella, Ignazio Infantino, Giovanni Pilato and Riccardo Rizzo. <i>A practical approach to Humanoid Introspection</i>	1005
Andrew Philippides, Bart Baddeley, Phil Husbands and Paul Graham. <i>A Situated and Embodied Model of Ant Route Navigation</i>	1007
G. Matthew Fricke, Francois Asperti-Boursin, Joshua Hecker, Judy Cannon and Melanie Moses. <i>From Microbiology to Microcontrollers: Robot Search Patterns Inspired by T Cell Movement</i>	1009
Sebastian Clarke, Frederic Labrosse, Vito Trianni and Elio Tuci. <i>An evolutionary approach to road following: a simulated case study</i>	1017
Joshua Hecker, Karl Stolleis, Bjorn Swenson, Kenneth Letendre and Melanie Moses. <i>Evolving Error Tolerance in Biologically-Inspired iAnt Robots</i>	1025
Christopher Schwarzer and Nico Michiels. <i>Conditions for Outperformance of Recombination in Online Evolution of Swarm Robots</i>	1033
Daniela Kengyel, Ronald Thenius, Karl Crailsheim and Thomas Schmickl. <i>Influence of a Social Gradient on a Swarm of Agents Controlled by the BEECLUST Algorithm</i>	1041
Vincenzo Fioriti, Stefano Chiesa and Fabio Fratichini. <i>Expanding the Time Horizon in Underwater Robot Swarms</i>	1049
A.E. Eiben, Nicolas Bredeche, Mark Hoogendoorn, Juergen Stradner, Jon Timmis, Andy Tyrrell and Alan Winfield. <i>The Triangle of Life</i>	1056

## **Biologically Inspired Engineering**

Martin Ullrich, Petra Haufová, Mandeep Singh and František Štěpánek. <i>Radiofrequency triggered enzymatic reaction inside hydrogel microparticles</i>	1064
--	------

## **Evolvable Hardware, Evolutionary Electronics & BioChips**

Leroy Cronin. <i>Linking Evolution in Silico, Hardware, and Chemistry to discover or engineer Inorganic Biology</i>	1066
Samuel Chapman, David Knoester, Arend Hintze and Christoph Adami. <i>Evolution of an artificial visual cortex for image recognition</i>	1067

Eiko Matsuda, Takeshi Mita, Julien Hubert, Mizuki Oka, Douglas Bakkum, Urs Frey, Hirokazu Takahashi and Takashi Ikegami. <i>Multiple Time Scales Observed in Spontaneously Evolved Neurons on High-density CMOS Electrode Array</i>	1075
---	------

## **Foundations of Complex Systems and Biological Complexity**

Steen Rasmussen, Harold Fellermann and Shinpei Tanaka. <i>Sequence selection and evolution in a binary polymer model</i>	1083
Gonzalo Ruz, Marco Montalva and Eric Goles. <i>On the preservation of limit cycles in Boolean networks under different updating schemes</i>	1085
Jack Hessel and Sherri Goings. <i>Using Reproductive Altruism to Evolve Multicellularity in Digital Organisms</i>	1091
Martin Biehl and Daniel Polani. <i>One way to see two in one</i>	1099

## **Mathematical Models for the Living Systems and Life Sciences**

Paul Calcraft, Phil Husbands and Andrew Philippides. <i>An Environmental Model of Self-Compatibility Transitions in the Solanaceae Plant Family</i>	1107
Jure Demšar and Iztok Lebar Bajec. <i>Family Bird: A Heterogeneous Simulated Flock</i>	1114
Pedro Mariano and Luis Correia. <i>Population Dynamics of Centipede Game using an Energy Based Evolutionary Algorithm</i>	1116
Tobias Meister, Ronald Thenius, Daniela Kengyel and Thomas Schmickl. <i>Cooperation of two different swarms controlled by BEECLUST algorithm</i>	1124

## **Music and the Origins and Evolution of Language**

Jonathan Impett and Leonardo Impett. <i>The perception of potential: interference, dimensionality and knowledge</i>	1126
---	------

## **Programmable Nanomaterials**

Leroy Cronin. <i>Programming the Assembly of Inorganic Nanomaterials Using Networked Chemical Reactions</i>	1132
Darko Stefanovic, Milan Stojanovic, Mark Olah and Oleg Semenov. <i>Catalytic Molecular Walkers: Aspects of Product Release</i>	1134

## ***Synthetic and Systems Biochemistry and Biological Control***

Leroy Cronin. <i>Synthetic biology manipulations in 3D printed wet-ware</i>	1142
Nathanael Aubert, Quang Huy Dinh, Masami Hagiya, Hitoshi Iba, Teruo Fujii, Nicolas Bredeche and Yannick Rondelez. <i>Evolution of Cheating DNA-based Agents Playing the Game of Rock-Paper-Scissors</i>	1143
Christoph Flamm, Chris Hemmingsen and Daniel Merkle. <i>Barrier Trees for Metabolic Adjustment Landscapes</i>	1151
Yoshihiro Shimizu and Yo Tanaka. <i>Reconstitution of the protein synthesis system on a glass microchip</i>	1159
Pasquale Stano, Erica D'Aguanno, Paolo Carrara, Alfred Fahr and Pier Luigi Luisi. <i>Recent advancements in synthetic cells research</i>	1160
Ben Shirt-Ediss, Ricard Solé and Kepa Ruiz-Mirazo. <i>Steady state analysis of a vesicle bioreactor with mechanosensitive channels</i>	1162

## ***Late Breaking Papers***

Inman Harvey. <i>How Fast Can We Evolve Something?</i>	1170
Önder Gürcan. <i>An Emergent Model for Mimicking Human Neuronal Pathways in Silico</i>	1172
Huy Tran and Andre S. Ribeiro. <i>Effects of inducer intake kinetics on the dynamics of gene expression</i>	1174
Cai Li, Robert Lowe and Tom Ziemke. <i>Crawling Posture Learning in Humanoid Robots using a Natural-Actor-Critic CPG Architecture</i>	1182
Ignazio Infantino and Riccardo Rizzo. <i>An Artificial Behavioral Immune System for cognitive robotics</i>	1191
Michael Spranger. <i>Evolutionary Explanations for Spatial Language - A Case Study on Landmarks</i>	1199
Alaa Abi Haidar, Adrien Six, Jean-Gabriel Ganascia and Veronique Thomas-Vaslin. <i>The Artificial Immune Systems Domain: Identifying Progress and Main Contributors Using Publication and Co-Authorship Analyses</i>	1206
Geoff Nitschke and Olaf Witkowski. <i>The Transmission of Migratory Behaviors</i>	1218
Genki Ichinose, Masaya Saito, Hiroki Sayama and David Sloan Wilson. <i>Adaptive long-range migration promotes cooperation under tempting conditions</i>	1220

Hector Zenil, Gordon Ball and Jesper Tegner. <i>Testing Biological Models for Non-linear Sensitivity with a Programmability Test</i>	1222
Chris Gordon-Smith. <i>SimSoup: Molecules Designed for Switchable Autocatalytic Memory</i>	1224
Roland Cazalis. <i>The emergence of life and evolution: Towards a categorial approach</i>	1232
Yao Yao, Kathleen Marchal and Yves Van de Peer. <i>Using novel bio-inspired principles to improve adaptability of evolutionary robots in dynamically changing environments</i>	1234
Peter Scully, Jingping Song, Jules Pagna Disso and Mark Neal. <i>CARDINAL-E: AIS Extensions to CARDINAL for Decentralised Self-Organisation for Network Security</i>	1235
<b>Author List</b>	1237

## ECAL 2013 Preface

ECAL 2013 continues with its mission to play a unique role as an information and knowledge sharing forum in synthetic life, where the wide range of its offerings allows ECAL attendants to learn and network.

After a pioneering phase lasted more than twenty years, ECAL will show the current state of the art of a mature and autonomous discipline, Artificial Life, that is collocated at the intersection between a theoretical perspective, namely the scientific explanations of different levels of life organizations (e.g., molecules, compartments, cells, tissues, organs, organisms, societies, collective and social phenomena), and advanced technological applications (bio-inspired algorithms and techniques to building-up concrete solutions such as in robotics, data analysis, search engines, gaming).

ECAL 2013, the twelfth European Conference on Artificial Life, is held in Taormina, on the beautiful island of Sicily, Italy, in September 2-6, 2013. While hosting the event, the city of Taormina will give the participants the opportunity to enjoy the richness of its historical and cultural atmosphere, its traditions, and the beauty of its natural resources, the sea, and Mount Etna the largest and active volcano of Europe (a UNESCO World Heritage site).

The 12th ECAL is truly “grand celebration” with hundreds of paper and poster presentations, *five focused tutorials* and an impressive constellation of *ten satellite workshops*. The scientific program has been designed to optimize the interactions on all levels. This year’s program includes papers from one of the largest pool of submissions (*267 submissions*).

Moreover, at ECAL 2013 we added *new and exciting tracks*: Adaptive Hardware & Systems and Bioelectronics, Adaptive Living Material Technologies & Biomimetic Microsystems, Artificial Immune, Neural and Endocrine Systems, Artificial Immune Systems - ICARIS, Bioinspired Learning and Optimization, Bioinspired Robotics, Biologically Inspired Engineering, Evolvable Hardware, Evolutionary Electronics & BioChips, Foundations of Complex Systems and Biological Complexity, Mathematical Models for the Living Systems and Life Sciences, Music and the Origins and Evolution of Language, Programmable Nanomaterials, and Synthetic and Systems Biochemistry and Biological Control.

So, in the ECAL 2013 program you will find research works written by leading scientists in the field, from *fifty different countries and five continents*, describing an impressive array of results, ideas, technologies and applications. The keynotes have always been one of the most important parts of ECAL. The nine keynote speakers of ECAL 2013 will focus on a wide spectrum of topics of our scientific and technological ecosystem. In particular, the nine keynote speakers are the following:

- *Roberto Cingolani*, Italian Institute of Technology - IIT, Italy
- *Roberto Cipolla*, University of Cambridge, UK
- *Dario Floreano*, Ecole Polytechnique Fédérale de Lausanne - EPFL, Switzerland
- *Martin Hanczyc*, University of Southern Denmark, Denmark
- *Henrik Hautop Lund*, Technical University of Denmark, Denmark
- *Keymeulen*, California Institute of Technology - CALTECH, USA
- *Steve Oliver*, University of Cambridge, UK
- *Bernhard Palsson*, University of California San Diego - UCSD, USA
- *Rolf Pfeifer*, Swiss Federal Institute of Technology - ETH, Switzerland

These speakers make a blend of all the Artificial Life topics, in particular their choice represents one of the first cross talk between synthetic (or systems biology) and robotics through the concept of artificial life. We expect both the round table with the speakers and the frequent non-formal interactions with the researchers attending the conference and the workshops will represent remarkable events!

This edition has highlighted a more profound integration of concepts and ideas from life sciences, artificial intelligence, mathematics, engineering and computer science than in the past. Furthermore, the integration between dry and wet lab biological results shows more progress. Although synthetic biology appears on a small number of

papers, it is already showing itself as a powerful engine for boosting new ideas into the ECAL breath of topics and new type of researchers, perhaps interested in designing life at different levels of complexity, will follow ECAL or will consider ECAL as top conference. As organisers of such important event we felt the duty to ask ourselves three questions:

Will this event attract young inquisitive minds?

Will this event be full of opportunity and career boosts for established researchers in the artificial life fields?

Will an ECAL author, or a student attending it, change the world?

We have shaped the conference to answer all these questions. We believe this conference is the place for rapid exchange of very innovative ideas in artificial life and therefore has a very important role in the current geography of places where innovation could take place. A young researcher will be exposed to the largest diversity of ideas in artificial life. The expectations are reflected by the larger number of registrations, papers, and satellite workshops with respect to the previous editions.

Finally, we would like to recognize the enormous efforts of the ECAL organizing committee who made ECAL possible by donating their time, expertise, and enthusiasm. Without their hard work and dedication, ECAL would not be possible. We also could not have organized ECAL 2013 without the excellent work of all of the program committee members, our workshop chair, tutorial chair, publicity chair, financial manager, conference secretary and local organizers. We would like to express our appreciation to the plenary speakers, to the tutorial speakers, to the workshop organizers, and to all the authors who submitted research papers to ECAL 2013.

ECAL is the premier event for science and technology in synthetic life, where scientists from all over the world meet to exchange ideas and sharpen their skills.

Taormina, September 2013

Pietro Liò, Orazio Miglino, Giuseppe Nicosia, Stefano Nolfi, and Mario Pavone

## Keynote Speakers

### Nanotechnologies for Humans and Humanoids

- **Roberto Cingolani** is the Scientific Director of IIT since December 8th, 2005. He earned a Ph.D. in Physics from the University of Bari in 1988. From 1989 to 1991, he was a staff member at Max Planck Institute for Festkörperforschung in Stuttgart (Germany). Since 2001, he has been member of various panels of the European Commission within the Sixth and Seventh Frame Programs in the field of Nanotechnology, New materials and New production systems. From 2002, he has been member of different panels of the Ministry of Research and University (Technical Secretariat for the National Research Plan, Commission for the selection of the Centres of Excellence). From 2000 to 2003, he was executive Vice-president of the National Institute for the Physics of the Matter (INFM). Founder and Director of the National Nanotechnology Laboratory (NNL) of INFM at University of Lecce in 2001, R. Cingolani is author or co-author of about 700 papers in international journals and holds about 30 patents in the fields of structural, optical and electronic properties of quantum nanostructures of semiconductors, molecular nanotechnologies for plastic photonics, OLED and plastic electronic devices (since 2000), bio-nanotechnologies, biomimetic systems, biological electronic devices (since 2003) and smart nanocomposite materials.

**Abstract** Nanotechnology is developing along a pathway which is parallel to that of evolution. Nanocomposite biomimetic materials, new sensing devices, interconnection of living cells (organs) and circuits are boosting the development of complex integrated systems such as humanoids and animaloids, whose performances, either biomechanic or cognitive, are continuously improving. A number of new technologies is thus first developed for these advanced machines, and then transferred to humans. Following the concept of the evolutionary pathway of technology we will briefly describe a few representative examples developed at IIT over the last few years:

- Artificial molecules and artificial antibodies, and their application to drug delivery and diagnostics
- Plantoids and robots with sensing roots
- Animaloid (quadrupeds) with advanced equilibrium and motion characteristics and their application to disaster recovery
- Humanoids with unprecedented cognitive and biomechanic capabilities, and their application as human companions, and for rehabilitation and prosthetic tools
- New biocompatible materials for soft machines

### Computer Vision: Making Machines that See

- **Roberto Cipolla** is a Professor of Information Engineering at the University of Cambridge and the Director of Toshiba's (Toshiba Research Europe) Cambridge Research Laboratory. He obtained a B.A. (Engineering) from the University of Cambridge in 1984 and an M.S.E. (Electrical Engineering) from the University of Pennsylvania in 1985. From 1985 to 1988 he studied and worked in Japan at the Osaka University of Foreign Studies (Japanese Language) and Electrotechnical Laboratory. In 1991 he was awarded a D.Phil. (Computer Vision) from the University of Oxford and from 1991-92 was a Toshiba Fellow and engineer at the Toshiba Corporation Research and Development Centre in Kawasaki, Japan. He joined the Department of Engineering, University of Cambridge in 1992 as a Lecturer and a Fellow of Jesus College. He became a Reader in Information Engineering in 1997 and a Professor in 2000. His research interests are in computer vision and robotics and include the recovery of motion and 3D shape of visible surfaces from image sequences; object detection and recognition; novel man-machine interfaces using hand, face and body gestures; real-time visual tracking for localisation and robot guidance; applications of computer vision in mobile phones, visual inspection and image-retrieval and video search. He has authored 3 books, edited 8 volumes and co-authored more than 300 papers.

**Abstract** Computer vision is the science and technology of making machines that see. The talk will begin with an overview of the state-of-the-art in the 3R's of computer vision: registration, reconstruction and

recognition and will include demonstrations of research projects from the University of Cambridge. and Toshiba Research Europe's Cambridge Laboratory.

The second part of the talk will introduce a novel digital interface - a talking head created by Toshiba Research Europe and the University of Cambridge. We have developed a system that can generate a realistic expressive talking head animation. The user enters input text and selects an expression such as 'happy' and 'angry' and the software makes a previously recorded face model talk at an unprecedented level of realism.

The face and speech model was learned from a large training dataset where sentences are spoken with a number of different emotions. In addition to a neutral style, the corpus includes angry, happy, sad, tender and fearful expressions. The realism of the animation is achieved by novel training and face modelling algorithms. A key technology behind training the expressive "talking head" model is Cluster Adaptive Training (CAT), which allows flexible control over the expressiveness of both the voice and the face model.

The new technology allows next generation interfaces. By combining speech and face video synthesis, so-called visual speech synthesis, interaction with computers will become more similar to interacting with another person. A demonstration will be included at the end of the talk.

## Bio-mimetic Flying Robots

- **Dario Floreano** is full professor, Director of the Laboratory of Intelligent Systems at Ecole Polytechnique Fédérale de Lausanne Switzerland (EPFL) and Director of the Swiss National Center of Robotics, a national strategic initiative bringing together all major robotics labs in Switzerland. His research focuses on the convergence of biology, artificial intelligence, and robotics. He has published more than 300 peer-reviewed papers, which have been cited more than 9K times, and four books on the topics of evolutionary robotics, bio-inspired artificial intelligence, and bio-mimetic flying robots with MIT Press and Springer Verlag. He is member of the World Economic Forum Council on robotics and smart devices, co-founder of the International Society of Artificial Life, Inc. (USA), co-founder of the aerial robot company senseFly Ltd (now member of the Parrot Group), advisor to the European Commission for Future Emerging Technologies, member of the editorial board of 10 professional journals, and board member of numerous professional societies in robotics and artificial intelligence. He is also active in the public understanding of robotics and artificial intelligence, delivered almost 150 invited talks worldwide, and started the popular robotics podcast Talking Robots (now The RobotsPodcast).

**Abstract** I will present an overview of my lab's efforts to develop autonomous robots capable of flying in cluttered environments and in safe interaction with humans. I will start by presenting miniature and small-size robots capable of performing collision-free flight and altitude control indoor and outdoor by means of insect-inspired vision and control. I will also present evolved and bio-mimetic strategies for coordination of outdoor flying robots. Finally, I will revisit the conventional concept of flying robots and describe recent work on the development of flying robots capable of surviving and exploiting collisions, just like insects do, in order to explore semi-collapsed buildings or extremely cluttered environments with no light.

## The real artificial lives of droplets

- **Martin Hanczyc** is an Associate Professor at the Institute of Physics and Chemistry at the University of Southern Denmark. He formally was an Honorary Senior Lecturer at the Bartlett School of Architecture, University College London and Chief Chemist at ProtoLife. He received a bachelor's degree in Biology from Pennsylvania State University, a doctorate in Genetics from Yale University and was a postdoctorate fellow under Jack Szostak at Harvard University. He has published in the area of protocells, complex systems, evolution and the origin of life in specialized journals including JACS and Langmuir as well as PNAS and Science. He is also a mentor for the first iGEM synthetic biology student team from Denmark. He is developing novel synthetic chemical systems based on the properties of living systems. Martin actively develops outreach for his research by giving several public lectures and collaborating with architects and artists in several exhibitions

world wide including the Architecture Biennale in Venice Italy in 2010 to bring experiments out of the lab and into the public space. His approach to science has been integrative, multidisciplinary and publicly visible with over 20 press items including Nature News, Scientific American, Discovery Channel, and BBC Radio. Martin gave an invited public lecture at TED in 2011, which now has over 500,000 views.

**Abstract** My work is focused on understanding the fundamental principles of living and evolving systems through experimental science. To this end, I build synthetic systems where dynamic life-like properties emerge when self-assembled systems are pushed away from equilibrium. I will present an experimental model of bottom-up synthetic biology: chemically-active oil droplets. This system has the ability to sense, metabolize and the potential to evolve. Specifically, I will present how sensory-motor coupling can produce chemotactic motile droplets and may form the basis for intelligent and self-replicating materials. In addition, I am involved with a new consortium to develop a robotic interface with feedback to maintain and manipulate the non-equilibrium state of the chemical systems in real time. This represents the integration of chemical, computational, and robotic artificial life.

## Playware ABC

- **Henrik Hautop Lund**, Technical University of Denmark, is head of the Center for Playware. He is World Champion in RoboCup Humanoids Freestyle 2002, has developed shape-shifting modular robots, and has collaborated closely on robotics, ALife and AI with companies like LEGO, Kompan, BandaiNamco, etc. for the past two decades. His Center for Playware at the Technical University of Denmark has a long track record of developing modular playware for playful contextualized IT training in Sub-Saharan Africa and for playful rehabilitation of mentally and physically handicapped children and adult in rural areas of Sub-Saharan Africa. These modular playware technology developments include I-Blocks (LEGO bricks with processing power) and modular interactive tiles (larger bricks for physical rehab). Further, with the development of East-Africa's first science and business park, local entrepreneurship has been fostered amongst students graduating from the university degree programs in contextualized IT. Combining such skills, it became possible to develop technical skill enhancing football games and global connectivity based on modular playware for townships in South Africa for the FIFA World Cup 2010. Lately, together with international pop star and World music promoter Peter Gabriel, it has been possible to develop the MusicTiles app as a music 2.0 experience to enhance music creativity amongst everybody, even people with no initial musical skills whatsoever. In all cases, the modular playware technology approach is used in a playful way to enhance learning and creativity amongst anybody, anywhere, anytime.

**Abstract** Embodied Artificial Life research has led to the development of playware defined as intelligent hardware and software that creates play and playful experiences for users of all ages. With recent technology development, we become able to exploit robotics, modern artificial intelligence and embodied artificial life to create playware which acts as a play force that inspires and motivates users to enter into a play dynamics. In such play dynamics, users forget about time and place, and simultaneously increase their creative, cognitive, physical, and social skills. The Playware ABC concept allows you to develop solutions for anybody, anywhere, anytime through building bodies and brains to allow people to construct, combine and create. Designing playware technology that results in specific behaviors of the user is not a trivial task, and it demands an array of background knowledge in a number of scientific fields. Indeed, definition of desired interactions and behaviors should arise from deep knowledge of the field of application (e.g. play of a specific user group, clinical knowledge of therapy of a specific patient group, professional music knowledge, and professional sport knowledge). In order to meet a practice, where several disciplines can join to develop such playware, and inspired by early artificial life work, we conceptualized the approach of modular playware in the form of building blocks. Building blocks should allow easy and fast expert-driven or user-driven development of playware applications for a given application field. The development of such modular playware technology takes its inspiration from modular robotics, human-robot interaction and embodied artificial life. In this talk, I will present the design principles for creating such modular playware technology with focus on the embodied AI principles that forms the foundation for the design principles of modular playware technology. I will exemplify the design principles with practical applications from the fields of play, sports, music, performance art, and health.

## Self-Repairing and Tuning Reconfigurable Electronics for Space

- **Didier Keymeulen** joined the computer science division of the Japanese National Electrotechnical Laboratory as senior researcher in 1996. In 1998 he moved to the California Institute of Technology and is currently principal member of the technical staff in the Bio-Inspired Technologies Group. He is leading several research tasks on adaptive computing, fault-tolerant electronics, and autonomous and adaptive sensor technologies. He was the electronics test lead of the tunable laser spectrometer (TLS) instrument on the 2011 Mars Science Laboratory (MSL) rover mission to Mars. He serves as chair, co-chair, and program-chair of the NASA/ESA Annual Conferences on Adaptive Hardware and Systems. Didier received his BSEE, MSEE and Ph.D. in Electrical Engineering and Computer Science from the Free University of Brussels, Belgium.

**Abstract** Space missions often require technologies not yet available for earth applications. This talk will present the development of self-reconfigurable electronics for few real-world problems encountered in space applications: survival in extreme environment, high precision inertial measurement for navigation, and in-situ adaptive control for space instruments. Radiation and extreme-temperature hardened electronics is needed to survive the harsh environments beyond earth's atmosphere. Traditional approaches to preserve electronics incorporate radiation shielding, insulation and redundancy at the expense of power and weight. This presentation will demonstrate the implementation of a self-adaptive system using a field programmable gate array (FPGA) and data converters which can autonomously recover the lost functionality of a reconfigurable analog array (RAA) integrated circuit (IC). The second application is related to the development of inexpensive, navigation grade, miniaturized inertial measurement unit (IMU), which surpasses the state-of-the art in performance, compactness (both size and mass) and power efficiency used by current space missions. The talk will explain a self-tuning method for reconfigurable Micro-Electro-Mechanical Systems (MEMS) gyroscopes based on evolutionary computation that has the capacity to efficiently increase the sensitivity of MEMS gyroscopes through in-situ tuning. Finally, we will address the path forward of using adaptive electronics for space.

## The Robot Scientist: Artificial Life Investigates Real Life

- **Steve Oliver** started to work on yeast as a graduate student and has studied it ever since, with occasional excursions into the filamentous fungi and even *Streptomyces* bacteria. The yeast genome-sequencing project was initiated in his lab in the mid-1980's when he started to sequence chromosome III. This turned into a major European Project, which eventually led to the sequencing of the entire yeast genome. He then took up the challenge presented by all the genes of unknown function revealed by the genome sequence, leading the EUROFAN Consortium that pioneered many of the 'omic and other high-throughput technologies in current use. His lab is dedicated to unravelling the workings of the yeast cell, using both top-down and bottom-up systems biology strategies. He is also concerned with developing yeasts as systems to both understand and combat human diseases, including through the use of automated ("Robot Scientist" methods in collaboration with Ross King's group in Aberystwyth). Finally, he takes an interest, at both the bioinformatic and experimental levels, in the evolution of genomes and networks, and is starting to apply this to mammalian systems. The models and experimental systems he uses with yeast sometimes lead in unexpected directions, such as predicting the impact of gene copy number variation in cancer, constructing network models to identify genes important in Alzheimer's Disease, or using yeast "surrogates" to screen for drugs against parasitic diseases .

**Abstract** Science involves the generation of hypotheses and the testing of those hypotheses by experiments whose results are recorded in sufficient detail to enable reproducibility. We developed the Robot Scientist "Adam" to advance the automation of both these processes. Adam has autonomously generated functional genomics hypotheses about the yeast *Saccharomyces cerevisiae*, and experimentally tested those hypotheses using laboratory automation. We, and others, have manually confirmed Adam's conclusions using additional experiments. To describe Adam's experiments we developed an ontology and logical language. The resulting formalisation involves over 10,000 different research units in a nested tree-like structure, ten levels deep, that relates the 6.6 million biomass measurements to their logical description. This formalisation describes how a machine discovered new scientific knowledge. We have now developed a second Robot

Scientist, “Eve”. Like Adam, Eve is a laboratory automation system that uses artificial intelligence techniques to discover scientific knowledge through cycles of experimentation. Eve automates the screening of candidate drugs, hit confirmation, and lead generation through QSAR learning and testing. Econometric modelling has identified the conditions where Eve outperforms standard automation. The second advance is the development of assays based on cellular analog computers. These utilize *Saccharomyces cerevisiae* synthetic biology to compute arbitrary Boolean functions of compound properties. These advances have enabled us to reposition multiple compounds as drugs likely to be effective at inhibiting specific enzyme targets in parasites causing tropical diseases.

## An Insight into Metabolic Requirements of Life

- **Bernhard Ø. Palsson** earned a Ph.D. from the University of Wisconsin in 1984. He held a faculty position at the University of Michigan from 1984 to 1995. He has been with UCSD since 1995. He is the author of over 350 peer reviewed scientific articles. He co-authored the text *TISSUE ENGINEERING*, Prentice Hall in 2004, and wrote *SYSTEMS BIOLOGY: properties of reconstructed networks*, Cambridge University Press in 2006, and *SYSTEMS BIOLOGY: simulation of dynamic network states*, Cambridge University Press in 2011. He sits on the editorial boards of several biology, bioengineering and biotechnology journals. Professor Palsson current research at UCSD focuses on 1) the reconstruction of genome-scale biochemical reaction networks (metabolism, transcriptional regulation & signaling), 2) the development of mathematical analysis procedures for genome-scale models (constraint-based and dynamic models), and 3) the experimental verification of genome-scale models with current emphasis on cellular metabolism and transcriptional regulation in *E. coli*, human pathogens, and organisms that are environmentally & bioprocess importance. He received an Institute of International Education Fellowship in 1977, Rotary Fellowship in 1979, a NATO fellowship in 1984, was named the G.G. Brown Associate Professor at Michigan in 1989, a Fulbright Fellow in 1995, an Ib Henriksen Fellow in 1996, the Olaf Hougen Professorship at the University of Wisconsin in 1999, the Lindbergh Tissue Engineering award in 2001, was named the Galetti Chair of Bioengineering in 2004, was elected into the National Academy of Engineering in 2006, received the UCSD Chancellor’s Associates award in Science and Technology in 2006, and was selected as the developer of one of the most influential technologies on Biotech over the past 10 years by Nature Biotechnology (March 2006). He was the Richard S.H. Mah Lecturer at Northwestern University in 2007, received the Ernst W. Bertner Memorial Award, from the MD Anderson in Houston in 2008, an honorary doctorate from Chalmers University in Gothenburg, Sweden, in 2009, the Marvin Johnson Award from the ACS in 2010, elected fellow of the AAAS on 2011, and received the ASM Promega Biotechnology Research Award in 2012. Professor Palsson is an inventor with over 35 U.S. patents, many of which are in the area of hematopoietic stem cell transplantation, cell culture technology, bioreactor design, gene transfer, cell separations, high-throughput single cell manipulation, pedigree-controlled drug screening, network reconstruction, laboratory adaptive evolution, in silico model building and metabolic engineering. He co-founded a biotechnology company, AASTROM BIOSCIENCES (NASDAQ: ASTM) in 1988, where he served as the Vice President of Developmental Research for two years. Dr. Palsson is the founder and co-founder of ONCOSIS, a company that was focused on the purging of occult tumor cells in autologous bone marrow transplants, renamed as CYNTELLECT, focusing on instrumentation for high-throughput screening and in situ cell sorting and processing, GENOMATICA, a company that is focused on the production of commodity chemicals by fermentation (a spin-off from UCSD), and GT LIFE SCIENCES, an in silico biology (a spin-off from Genomatica).

**Abstract** Whole genome sequencing has enabled us to understand the basic gene portfolio of living cells. A class of gene products that are well known are metabolic enzymes. Based on genome annotation and legacy data it has become possible to reconstruct metabolic networks. These networks are amenable to modeling as systems and have given the basis for in silico cells that are the best representation of their living counterparts. We will discuss the conceptual basis for this field, the difficult and laborious process of network reconstruction, and give examples of the use of in silico cell simulations.

## “Soft Robotics” - the next generation of intelligent machines

- **Rolf Pfeifer** Master’s degree in physics and mathematics and Ph.D. in computer science (1979) from the Swiss Federal Institute of Technology (ETH) in Zurich, Switzerland. Three years as a post-doctoral fellow at Carnegie-Mellon and at Yale University in the US. Since 1987: professor of computer science at the Department of Informatics, University of Zurich, and director of the Artificial Intelligence Laboratory. Visiting professor and research fellow at the Free University of Brussels, the MIT Artificial Intelligence Laboratory in Cambridge, Mass., the Neurosciences Institute (NSI) in San Diego, the Beijing Open Laboratory for Cognitive Science, and the Sony Computer Science Laboratory in Paris. Elected “21st Century COE Professor, Information Science and Technology” at the University of Tokyo in 2004. In 2009: visiting professor at the Scuola Superiore Sant’Anna in Pisa, and at Shanghai Jiao Tong University in China; appointed “Fellow of the School of Engineering” at the University of Tokyo. Currently: Deputy Director of the NCCR Robotics, the “National Competence Center for Research in Robotics” in Switzerland. Research interests: embodied intelligence, biorobotics, morphological computation, modular robotics, self-assembly and educational technology. Authored books: “Understanding Intelligence”, MIT Press, 1999 (with C. Scheier), “How the body shapes the way we think: a new view of intelligence,” 2007 (with Josh Bongard) MIT Press (popular science style), “Designing intelligence - why brains aren’t enough” (short version - with Josh Bongard and Don Berry, e-book), and “La révolution de l’intelligence du corps”, 2012 (“The revolution of embodied intelligence”; with Alexandre Pitti) (in French). Lecture series: “The Shanghai Lectures”, a global mixed-reality lecture series on embodied intelligence, broadcast in 2012 from the University of Zurich, and Shanghai Jiao Tong University, China in cooperation with other universities from around the globe. World exhibition: ROBOTS ON TOUR - World Congress and Exhibition of Robots, Humanoids, Cyborgs, and more. 9 March 2013, Zurich (Puls 5): robotsontour.org.

**Abstract** Researchers from robotics and artificial intelligence increasingly agree that ideas from biology and self-organization can strongly benefit the design of autonomous robots. Biological organisms have evolved to perform and survive in a world characterized by rapid changes, high uncertainty, indefinite richness, and limited availability of information. The term “Soft Robotics” designates a new generation of robots capable of functioning in the real world by capitalizing on “soft” designs at various levels: surface (skin), movement mechanisms (muscles, tendons), and interaction with other agents (smooth, friendly interaction). Industrial robots, in contrast, operate in highly controlled environments with no or very little uncertainty. By “outsourcing” functionality to morphological and material characteristics - e.g. to the elasticity of the muscle-tendon system - the distinction between control and to-be-controlled, which is at the heart of manufacturing and control theory, breaks down and entirely new concepts will be required. In this lecture I will argue that the next generation of intelligent machines - robots - will be of the “soft” kind and I will explore the theoretical and practical implications, whose importance can hardly be over-estimated. I will be using many examples and case studies. In particular I will be introducing the tendon-driven “soft” robot “Roboy” that we have been developing in our laboratory over the last few months. Although many challenges remain, concepts from biologically inspired “soft” robotics will eventually enable researchers to engineer machines for the real world that possess at least some of the desirable properties of biological organisms, such as adaptivity, robustness, and versatility.

## Tutorials

- **Cell Pathway Design for Biotechnology and Synthetic Biology**

Claudio Angione, Jole Costanza, Giovanni Carapezza, Pietro Lió and Giuseppe Nicosia

*Description.* We will introduce the BioCAD framework that we have developed to analyse, optimise and re-design biological models. The framework includes 1) Multi-Objective Optimisation, 2) Sensitivity, 3) Identifiability and 4) Robustness analyses. More specifically, we will present single- and multi-objective optimization algorithms able to handle genetic strategies or uptake rates in a given model. We will show that the condition of Pareto optimality can be relaxed (e.g., epsilon-dominance) to include suboptimal points that can be used to boost the algorithm in its convergence process. The Sensitivity Analysis (SA) is used to compute an index for each parameter that indicates its influence in the model. The Identifiability Analysis (IA) detects functional relations among decision variables through a statistical analysis on the values after and before the optimisation. The Robustness Analysis (RA), Local, Global and Glocal robustness, proves useful to assess the fragileness and robustness of the Pareto optimal solution (or of a given feasible solution) as a result of a perturbation occurring in the model. Our methodology is suitable for (i) any model consisting of ordinary differential equations, differential algebraic equations, flux balance analysis and gene-protein reaction mappings and for (ii) any simulator (e.g., SBML, MatLab, NEURON, C/C++ program). In the tutorial, we will show how these techniques offer avenues to systematically explore, analyse, optimise, design and cross-compare biological models (e.g., metabolic models, gene regulatory networks).

- **Exploring Prebiotic Chemistry Spaces**

Jakob L. Andersen, Christoph Flamm, and Daniel Merkle

*Description.* We have developed a graph grammar based formalism to model chemical transformations. Within our formalism molecules are treated as vertex and edge labeled graphs and reactions (between molecules) are handled as graph rewrite. This approach nicely captures the algebraic properties of real chemistry, where novel molecules can be produced during chemical reactions. Graph grammars, i.e. a set of reaction rules and starting molecules, are very compact representations of entire chemical space. These spaces can contain interesting chemical transformation patterns such as auto-catalytic sub-networks, or alternative routes to molecules of interest. Such sub-networks are usually hard to find due to the vastness of chemical spaces. The situation is especially bad in the origin of life realm, where several putative prebiotic chemistries, all combinatorial complex in nature, have been suggested. Efficient computational methods for constructing and exploring chemical spaces are therefore essential to explore alternative scenarios, or to shade light on potential chemical processes which could have resulted in the emergence of life. The tutorial will offer a mix between short background presentations and accompanying practical examples. To ensure that attendees have the right libraries and programs available, we will provide a working environment. The attendees will learn (i) how to translate chemical reactions to graph rewrite rules, (ii) various methods to explicitly construct chemical spaces (iii) query the chemical space for interesting sub-networks.

- **Designing Adaptive Humanoid Robots Through the FARSA Open-Source Framework**

Gianluca Massera, Tomassino Ferrauto, Onofrio Gigliotta and Stefano Nolfi

*Description.* In this tutorial we will illustrate FARSA, an open-source tool available from <http://laral.istc.cnr.it/farsa/>, that allows to carry on research on Adaptive Robotics. Farsa allows to simulate different robotic platforms (the iCub humanoid robot, and the Khepera, e-Puck, and marXbot wheeled robots), design the sensorimotor system of the robots, design the environment in which the robots operate, perform collective experiments with many interacting robots, design the robots' neural controllers, and allow the robots to develop their behavioural skills through an evolutionary or learning process. It is a cross-platform framework, that works on Linux, Windows and Mac on both 32bit and 64bit systems, constituted by a collection of integrated open-source object-oriented C++ libraries. The framework comes with a powerful graphical application that allow to create and run a large variety of experiments and to analyse and test the obtained results. Furthermore, FARSA has a plugin mechanism that allow to add new features (new robots, new motors, new neural networks, new learning algorithms, etc) that are integrated and accessible

by the graphic interface without modifying and recompiling the core code. FARSA is well documented, easy to use and comes with a series of exemplificative experiments that allow users to quickly gain a comprehension of the tool and a base for running a large spectrum of new experiments that can be set up simply by changing the available parameters. The aim of the tutorial is that to allow also non-technical user to quickly acquire the knowledge required to use the tool and personalize it to specific research interests.

- **Next Generation Sequencing Data Production, Analysis, and Archiving**

Heiko Muller and Luca Zammataro

*Description.* Application of Next Generation Sequencing (NGS) in cancer research is becoming routine in laboratories all over the world and new applications of NGS are being developed at increasing speed. The generation, analysis, interpretation, and storage of NGS data poses a number of technical challenges. Here, the computational infrastructure and the analysis pipelines used at the Center of Genomic Science in Milan (Italian Institute of Technology) are described. In the second part, meta-analysis approaches facilitating the interpretation of NGS data are being discussed. In particular, we will highlight international efforts in cancer genomics aimed at collecting genomic data (e.g. somatic mutations, gene expression, epigenetic modifications, copy number variation) from cancer samples and correlating these data with clinical parameters with the aim of identifying novel biomarkers of cancer subtypes and eventually novel targets for therapeutic intervention. The joined analysis of genomic data of various kinds is a field of active research that is often referred to as Integromics. We will provide an overview of the current state of the art and illustrate the use of selected novel bioinformatic resources of general interest.

- **PyCX: A Python-Based Simulation Code Repository for Complex Systems Education**

Hiroki Sayama

*Description.* This tutorial will introduce PyCX, an online repository of sample codes, all written in plain Python, of various complex systems simulation, including iterative maps, cellular automata, dynamical networks and agent-based models. These sample codes are designed as educational materials so that students can gain practical skills for both complex systems simulation and computer programming simultaneously. The target audience of this tutorial will primarily be educators and researchers who teach complex systems-related courses and thus need simple, easy-to-understand examples of complex systems simulation. The tutorial will also be helpful for students who want to learn basics of writing complex systems simulation themselves. Prior knowledge of Python is helpful but not required. Participants should bring their own laptops to the tutorial so they can work on hands-on coding activities.

## Satellite Workshops

- *A TRUCE workshop on Unconventional Computing in 2070*  
Martyn Amos
- *Artificial Life Based Models of Higher Cognition*  
Onofrio Gigliotta and Davide Marocco
- *Artificial Life in Massive Data Flow*  
Takashi Ikegami, Mizuki Oka, Norman Packard, Mark Bedau and Rolf Pfeifer
- *Collective Behaviours and Social Dynamics*  
Stefano Nolfi, Marco Dorigo, Francesco Mondada, Tom Wenseleers, Vito Trianni and Michael Spranger
- *2nd International Workshop on the Evolution of Physical Systems*  
John Rieffel, Nicolas Bredeche, Jean-Baptiste Mouret and Evert Haasdijk
- *ERLARS 2013 - 6th International Workshop on Evolutionary and Reinforcement Learning for Autonomous Robot Systems*

## Abstract

Cooperation is vital for maintaining the integrity of complex life forms. In many cases in nature cooperation manifests itself through constituent parts performing different, but complementary, functions. The vast majority of studies on the evolution of cooperation, however, look only at the special case in which cooperation manifests itself via the constituent parts performing identical tasks. In this paper we investigate a class of games in which the socially optimal behaviour has the property of being heterogeneous. We show that this class of games is equivalent to a region of ST space (the space of normalised two-player games characterised by the ‘sucker’ and ‘temptation’ payoffs) which has previously been dismissed. We analyse, through a simple group selection model, properties that evolving agents would need to have in order to “solve” this dilemma. Specifically we find that positive assortment on pure strategies may lower mean individual payoff, and that assortment on mixed strategies will increase payoff, but not maximise it.

## Introduction

Division Of Labour (DOL) is ubiquitous in the biological world. Social insects often have specialised castes for performing individual tasks (Hölldobler and Wilson, 2009). Multicellular organisms exhibit high levels of cell differentiation. Colonial marine invertebrates have differentiated parts which also specialise (Dunn and Wagner, 2006). Even bacteria have been shown to exhibit specialisation (Crespi, 2001). Arguably DOL is one of the major benefits to group living. It has long been recognised that specialisation may result in gains in efficiency; the idea can be traced at least as far back as Adam Smith’s *Wealth of Nations* (Smith, 1776). However, with all group living comes the potential for the emergence of cooperative dilemmas. Whenever a task is broken down into smaller parts the products of the sub-tasks must be shared or distributed. This potentially opens the door to free riders who benefit from the distribution of the products of labour, without contributing to its costs.

There are a growing body of artificial life studies concerning the evolution of the division of labour. Specifically authors have addressed: the mechanisms by which a division of labour can occur (Goldsby et al., 2012), the evolu-

tionary pathway to the emergence of complex internal features (Lenski et al., 2003), the evolution of differentiation in multicellular organisms (Ray and Hart, 1999), the role of gene networks in multicellular development (Joachimczak and Wróbel, 2008) and the evolutionary role of asymmetric cell division (Hotz, 2004).

DOL is also one of the key theoretical ideas behind the major evolutionary transitions research program (Maynard Smith and Szathmari, 1997). A major transition is one in which biological entities which were, preceding the transition, able to replicate as individuals are, after the transition, only able to replicate as part of a larger whole. DOL is likely to be one of the key concepts that leads to a deeper understanding of the major transitions. As increased specialisation develops, individuals become increasingly dependent upon one another, to the point where it is no longer sensible to regard them as functionally independent entities. For example, a potentially defining characteristic of certain types of major transition (i.e. the fraternal transitions (Queller, 1997)) is a reproductive division of labour (Michod, 2006).

Cooperative dilemmas are the class of games in which well-mixed populations of agents evolve to a state which does not maximise mean individual payoff. Theoretical considerations regarding the evolution of cooperation posit a game in which the socially optimal behaviour, for the population, is for every agent to perform the action labelled as cooperate. These set of games are cooperative dilemmas if there exists an ESS which is different from total cooperation. That is that under freely evolving conditions the population is composed either partially or entirely of defectors. Models of the evolution of cooperation then typically consider extensions of the underlying game which result in an increase in the level of cooperation. A common way in which this is achieved is through imposing population structure which leads to positive assortment and hence to an increase in cooperation (see for instance: Nowak and May (1992); Maynard Smith (1964)). Here positive assortment means that like strategies play each other more often than would be expected from random interactions. (For general arguments concerning the role of assortment in the evolution

of cooperation see: Eshel and Cavalli-Sforza (1983); Queller (1985); Dugatkin and Mesterton-Gibbons (1992); Godfrey-Smith (2008)).

Despite the large variety of computational and analytic models along these lines all such studies are built on a common assumption: namely the final optimal state is a homogeneous one in which all individuals play the same strategy. However, many situations in nature can be said to be in cooperative states, but between individuals or components which are not exhibiting homogeneous behaviours. To the best of the authors' knowledge none of these evolutionary game-theoretic investigations have considered situations in which a heterogeneous final state is desirable.

This paper firstly identifies the class of games in which a mixed state is socially optimal, i.e. games in which a division of labour may evolve. We show that these games are related to the conventional cooperative dilemmas. We then go on to present two models to illustrate some key points. The first model challenges the assumption that positive assortment on pure strategies will lead to an increase in the population's mean payoff. The second model extends this by introducing the additional assumption of mixed strategies. The model shows that positive assortment on mixed strategies does lead to an increase in the population's mean payoff. Finally we sketch some further theoretical considerations which show that, although positive assortment on mixed strategies does lead to an increase in payoff, it is not the highest payoff that can be reached under any circumstance. Specifically in order to maximise average payoff individuals would have to control not just the frequency of strategies, but the frequency of interactions within the population. In this case a negative assortment on social strategies is optimal for the population; however, we show that it is not evolutionarily stable. In order for this optimal configuration to be stable it is necessary to have a higher level positive assortment on genotypes which provides a lower level negative assortment of phenotype/social strategy.

### Division of Labour Games

We now outline a formalism which enables us to think about the division of labour in the simplest non-trivial case.

Consider a situation in which individuals meet and perform one of two tasks: A or B. Each task bestows a benefit to both of the individuals involved in the interaction. The benefits are given by  $b_A$  and  $b_B$  respectively. Each individual must bear the cost of their performed task themselves. Costs are given by  $c_A$  and  $c_B$ . However, if both individuals perform the same task the cost of that task is shared between them. In addition, there is a synergistic benefit which is the benefit of having both tasks performed together:  $\delta$ . We consider the cases in which A has a higher cost but also a higher benefit than B, i.e.  $c_A > c_B$  and  $b_A > b_B$ .

An example of the situation described above might go as follows. Two human individuals living in the same tribe may

perform one of two tasks. Task A is to go and hunt for meat. Task B is to build a fire. Hunting comes at an extra cost to the individual either because it requires more energy or because it is inherently riskier. The benefit of hunting is meat. Building the fire has a lower, but non-zero, cost. The benefit of building the fire is warmth. We assume that the meat is more valuable than the warmth, but that both tasks provide some benefit in isolation. In this instance the synergistic benefit,  $\delta$ , is that of having cooked meat. It is the benefit above and beyond that of the sum of the two benefits in isolation. We are assuming here that the benefits are non-excludable, that is that the hunter could not stop the fire builder from taking meat, and vice versa. This cartoon is an aid to understanding; the essential features of the situation are represented via the payoff matrix:

	A	B
A	$b_A - c_A/2$	$b_A + b_B + \delta - c_A$
B	$b_A + b_B + \delta - c_B$	$b_B - c_B/2$

Given that games have two arbitrary degrees of freedom we will assume that:  $b_A - c_A/2 = 1$  and  $b_B - c_B/2 = 0$ . We can thus rewrite the above payoff matrix as:

	A	B
A	1	$1 - r + \delta$
B	$1 + r + \delta$	0

Where  $r = \frac{1}{2}(c_A - c_B)$ . This reduces to the 1 dimensional parameterisation of the snowdrift game if  $\delta = 0$  (Hauert, 2004). Conceptually we may also think of the story behind the snowdrift game as the special case in which task B is the task of doing nothing with no benefit and no cost.

We can trivially see that this game represents a region of ST space using  $S = 1 - r + \delta$  and  $T = 1 + r + \delta$ . For an explanation of ST space see Santos et al. (2006).

Note that  $r$  is the difference in cost between performing the two tasks, and can thus be thought of as parameterising the severity of the dilemma.  $\delta$  represents the synergistic benefits of having both tasks performed.  $\delta > 0$  corresponds to the region  $S + T > 2$ .

Figure 1: The location of all games in ST space. Previously the top right quadrant was simply referred to as the snowdrift game. Here we split this region into two. Snowdrift A corresponds to games which are snowdrift games but not DOL games. Snowdrift B refers to snowdrift games which are also division of labour games. The remainder of this paper is concerned with the region labelled snowdrift B.

### Cooperative Dilemmas

The previous section introduced a class of games which are formally equivalent to the region of ST space in which  $S + T > 2$ . We shall refer to these games as Division of Labour games. Snowdrift games are defined by  $0 < S < 1$  and  $T > 1$ . We shall focus our investigation on the class of games which are both snowdrift games and DOL games (note that neither one implies the other).

ST space was conceived of in order to systematically investigate all classes of cooperative dilemmas. Some authors (see for instance Macy and Flache (2002)) specifically exclude the region  $S + T > 2$  from the definition of cooperative dilemmas. We find this exclusion somewhat artificial. The essence of a cooperative dilemma is a situation in which evolution leads to a state which does not maximise mean individual payoff. It just so happens that in conventional cooperative dilemmas social welfare is maximised by every agent cooperating, but this is by no means an essential part of the argument. Let us define the Socially Optimal Frequency (SOF) as the frequency of cooperate (or type A in the language of DOL games) which maximises the mean payoff of the population under well mixed conditions. We then define a cooperative dilemma as one in which  $\text{SOF} \neq \text{ESS}$ .

We now need to derive an equation for the SOF in terms of  $S$  and  $T$ . To do this note that the mean fitness of the population is given by:

$$\bar{f} = f_c \rho_c + f_d \rho_d \quad (1)$$

We consider a fixed population size so that  $\rho_d = 1 - \rho_c$ . Fitnesses are given by  $f_c = \rho_c + S\rho_d$  and  $f_d = T\rho_c$ . We then arrive at a formula for average fitness in terms of density of cooperators ( $\rho$ ):

$$\bar{f} = \rho(S + T + \rho(1 - S - T)) \quad (2)$$

The SOF is the maximum of this function for  $\rho \in [0, 1]$ . It is straight forward to prove that:

$$\text{SOF} = \begin{cases} \frac{S+T}{2(S+T-1)} & S+T > 2 \\ 1 & S+T \leq 2 \end{cases} \quad (3)$$

The ESS of the snowdrift game is (Nowak, 2006a):

$$\text{ESS} = \frac{S}{S+T-1} \quad (4)$$

for DOL games which are also snowdrift games the ESS is only equal to the SOF in the very special instance in which  $S = T$ . Thus, by our slightly broader definition, DOL games are cooperative dilemmas.

Figure 2: Left: The equilibrium frequency of cooperate. Right: the SOF, note that in the top right hand corner this is not equal to 100% cooperation.

### Model

In this section we demonstrate that positive assortment on pure strategies is only sufficient in allowing populations to reach the SOF in the non-generic case in which  $\text{SOF} = 1$ . We go on to show that positive assortment is still one of the key elements in allowing populations to reach the SOF. However, in this case the assortment must be on something other than pure social strategies.

We implement two generational GAs (labelled model I and II) to illustrate some key points. In both cases we construct a scenario in which one can exogenously control the level of assortment in a population of evolving individuals and measure the total payoff in the population. Model I serves as a control for model II. With model I we allow only pure strategies which are only able to perform one of two tasks, A or B, for the entirety of their lifetime. In model II we lift this assumption and allow for mixed strategies. Specifically a genotype specifies not a task A or B, but a probability,  $p \in [0, 1]$ , which determines how often task A is

performed. Apart from this difference models I and II have the same underlying structure.

The models consist of two distinct phases, a group phase and a population phase. Rounds of the game during one generation occur in  $\tau$  discrete time steps; the first  $X$  time steps within groups, the remaining  $\tau - X$  time steps within the fully mixed population. If  $f_G$  is fitness acquired within the group phase and  $f_P$  fitness acquired within the population phase then total fitness,  $f_T$ , is given by:

$$f_T = \frac{X}{\tau} f_G + \frac{\tau - X}{\tau} f_P \quad (5)$$

There are  $N_G$  groups consisting of  $g$  players in each group. Individuals acquire fitness over both stages of the generation.  $N_G$  individuals are chosen at the end of the population stage via fitness proportionate selection and go on to form new groups. The founding individuals immediately replicate  $g - 1$  times so that the groups are composed of  $g$  clonal individuals. Figure 3 shows schematics for the two models.

Figure 3: Schematics for models I and II respectively.

We consider the model in two different manners. First of all, we model the situation through numerical integration of the relevant replicator equation (see appendix A). This corresponds to infinite populations without mutations. Secondly, we model the system via an agent based simulation with finite population and mutations. The two approaches show good agreement in final results.

In the agent-based model there is mutation. Mutation

leads to one of the individuals in the group stage being genetically different to their parent.

In model I we model mutation by allowing an A to create a B, and vice versa, with a probability  $\mu = 1 \times 10^{-2}$ . In model II, with probability  $\mu = 5 \times 10^{-2}$ , an individual is born with a value of  $p$  which differs from its parent by an amount chosen from the random uniform distribution  $[-0.1, 0.1]$ . Mutations are capped to physically meaningful ranges (i.e. between 0 and 1) if they mutate outside of this range.

Figure 4: Top: The mean value of  $p$  at equilibrium for a range of values of  $\alpha$  in model II. The lower dotted line is the ESS and the upper one the SOF. Bottom: Fitness at ESS for the two models. The solid line is generated from the predictions of the analytic model, points from the agent based model. Clearly agents in model II are at an advantage over those in model I.  $(r, \delta) = (0.5, 0.5)$ .

This group structuring model allows us to fine-tune the level of assortment on the population. It bears some similarities to the hay-stack model (Maynard Smith, 1964). However, within a group there is no selection, as all members are clonal. The groups are formed from a founder and serve only to limit the interactions of individuals to a certain, non-random, subset of the population. In this sense the models bear some conceptual similarities to the ones discussed in Godfrey-Smith (2008). The qualitative results would be repeatable with any of the standard repertoire of “evolution of

cooperation” models (Nowak, 2006b). This particular model is not chosen for biological realism, but because the essential property of population structure leading to positive assortment is completely transparent. The models have the convenient feature of being able to tune the level of population structure via the parameter  $\alpha = x/\tau$ .

Previously the distinction between pure and mixed strategies has not been important. In a snowdrift game the frequency of cooperate at the ESS can represent either the frequency of pure strategy cooperators within the population or the average value of  $p$  (the probability of cooperating) within a population of mixed strategy individuals (Maynard Smith, 1982, p.17). These two models show that this distinction is important when playing a game in which  $\text{SOF} \neq 1$ .

In model I there is a one-to-one correspondence between the genotype and the social strategies A and B. Group structure provides only positive assortment on pure strategies. Assortment is needed for the evolution of cooperation. However, positive assortment leads to groups comprised only of one type.

It is important to realise that model II provides assortment on mixed strategies rather than on the pure phenotypes A and B. This is crucial to the following results.

Figure 5: The mean fitness at ESS. Left column is for pure strategies, as in model I, right column is for mixed strategies, as in model II. Going down the page the figures correspond to increasing levels of  $\alpha$ . Top:  $\alpha = 0$ , middle:  $\alpha = 0.25$  and bottom:  $\alpha = 0.5$ .

Figure 4 shows the results of the two versions of the model. There are 125 groups composed of 5 individuals each. The simulation is run for  $5 \times 10^6$  generations and the

average value of  $p$  (probability of playing strategy A) over the entire population is recorded. We find that groups in model II evolve towards the SOF for larger values of  $\alpha$  (the degree of population structure). As expected with  $\alpha = 0$  the population simply evolves to the ESS in both models.

We plot the relative fitness for models I and II for increasing  $\alpha$  to illustrate the fact that mixed strategies are at an evolutionary advantage over pure ones. Note that by construction pure strategies only interact with types of the same pure strategy within groups (in model I). In the case where the socially optimal solution was pure cooperate the ability to form pure groups is sufficient to solve the dilemma. However, in general these are a special type of game. For DOL games, in which a mix of strategies is desirable, mixed strategies can outperform pure ones.

Figure 5 shows the fitness at ESS for models I and II for all games parameterised via  $r$  and  $\delta$ . Interestingly positive assortment on pure strategies can actually be detrimental to the population’s payoff if  $\delta$  (the synergistic benefit to heterogeneous behaviours) is sufficiently high. The higher the synergistic benefit is the greater the advantage of having mixed strategies.

## Group Phenotypes

Groups composed of mixed strategies do not maximise social welfare. The reason for this is that they are unable to control their internal structure or organisation. In this section we formalise this point. We leave a detailed specification and analysis of a model for a forthcoming work.

In a well-mixed population the parameter  $\rho$  (frequency of type A) characterises the state of the system. However, if interactions are not random then  $\rho$  on its own is insufficient. We also need to know the frequency of the different types of within-group interactions. In principle there are three types of interactions: (A-A, A-B and B-B). If the total number of interaction of all types is fixed, then knowing the fractional density of each type will specify the state of the group. We will denote these three densities as  $\phi_{AA}$ ,  $\phi_{AB}$  and  $\phi_{BB}$ . However, it is sufficient to know only one of these. Let us then use  $\phi_{AB}$  and drop the subscript. We shall define the *group phenotype* as a point in the space  $(\rho, \phi)$ . The following formulae show how the densities of all types of interaction can be found from these two variables.

$$\phi_{AA} = \rho - \frac{1}{2}\phi \quad (6)$$

$$\phi_{AB} = \phi \quad (7)$$

$$\phi_{BB} = 1 - \rho - \frac{1}{2}\phi \quad (8)$$

Notice that  $\phi$  is confined within certain ranges based on  $\rho$ . Specifically  $0 \leq \phi \leq 2\text{Min}\{\rho, 1 - \rho\}$ .  $\phi$  is equivalent to certain measures of linkage disequilibrium (see for instance Hartl and Clark (1998)). For interesting parallels between population genetics and the evolution of cooperation

see Gardner et al. (2007).

The previous section considered the cases in which groups only had control over the parameter  $\rho$  and had no way of controlling the internal composition of within group interactions. In this case they were confined to have a value of

$$\varphi = \varphi^{(R)} = 2\rho(1 - \rho) \quad (9)$$

where R stands for random. Thus the SOF (Socially Optimal Frequency) corresponds to the fittest group with random internal interactions. Let us also define the Optimal Group Phenotype (OGP) to be the point in  $(\rho, \varphi)$  space which maximises average fitness. To see this, note that average fitness is given by:

$$\bar{f} = \rho + \frac{1}{2}(S + T - 1)\varphi \quad (10)$$

for games in  $(S, T)$  space. The OGP is then given by:

$$OGP = \begin{cases} (1, 0) & S + T < 2 \\ (1/2, 1) & S + T > 2 \end{cases} \quad (11)$$

thus in DOL games a group which maximises the amount of A-B links at the expense of all other types of interactions is the one which maximises group fitness.

Figure 6: Left: The average fitness in terms of  $\rho$  and  $\varphi$ , for a certain game in which  $R + T > 2$ . Right: the absolute difference between the fitness of the two phenotypes A and B (assuming that the group is composed of pure strategy individuals). The dotted line marks  $\varphi^{(R)}$ . Circled points correspond to A: The ESS under well mixed conditions, B: The SOF, C: The optimal point for pure groups and D: the OGP. Note: if  $S + T < 2$  B, C and D coincide. The fact that stability is non-zero at points B and D shows that these situations are fundamentally unstable without the addition of extra assumptions.

With reference to figure 6 model I of the previous section was only able to evolve to point C, model II was able to do

better and reach point B. However, neither model produced groups who were able to reach point D. This is the subject of a forthcoming work in which we investigate the effects of developmental or aggregational processes.

## Discussion

Kant said:

“Act only according to that maxim whereby you can, at the same time, will that it should become a universal law.”

In a fully assorted population Kant’s principle is not only morally commendable, but it is also entirely sensible. Given that you will only meet individuals who are the same as you it makes sense to perform social actions which are beneficial to be on the receiving end of. Thus it would seem that positive assortment is *the* answer to the evolution of cooperation.

On the other hand gains from specialisation occur via a collection of *different* types of individuals. We have seen that a division of labour game may be a cooperative dilemma. There are two needs which seem to be fundamentally at odds with each other: firstly, the need for positive assortment to alleviate the cooperative dilemma, and secondly, the need for negative assortment in order to gain from specialisation. This is the fundamental problem of the evolution of the division of labour. How does nature have her cake and eat it? That is how does evolution create the positive assortment necessary to alleviate the cooperative dilemma, but at the same time maintain the diversity needed to benefit from a division of labour?

It could be argued that many interesting and complex aspects of the biological world are about solving this problem. Phenotypic plasticity is a way in which a social strategy is able to become decoupled from the genotype which underlies it (Gavrilets, 2010). Thus we can have assortment on genotype without assortment on phenotype (as in model II), which goes some way to alleviating the problem of the division of labour. This is the key point which the models presented here attempt to illustrate. One way of expressing this would be to say that the social strategy has become de-Darwinised (*sensu* Godfrey-Smith (2009)). In division of labour games the optimal configuration involves As interacting with Bs to the exclusion of all other types of interaction. However, in this situation the fitness acquired by the phenotype B will always outweigh that acquired by A (because in our framework  $T > S$ ). Thus the optimisation of the higher level entity, the group, is in direct conflict with that of the lower level entities, the individuals. The only way in which higher level optimisation can occur is if selection does not act directly on the frequency of the constituent types A and B. This is what we mean by de-Darwinisation. A potential way for this to occur is through a genotype-phenotype map which is not one-to-one (i.e. a genotype may specify more

than one phenotype). In this case, although social interactions lead to Bs having a higher fitness, the configuration is sustainable because natural selection does not “see” the phenotypes A and B, it only “sees” genotypes which specify certain frequencies and organisations of social strategies. We see the concept of de-Darwinisation as a powerful conceptual tool for understanding the emergence of higher levels of biological organisation.

An ALife approach will doubtless be one of the key theoretical tools in our quest to understand biological organisation. Simulation is necessary not only because the processes of interest are obscured by time, but also because we only have one truly independent example of life. What we really want to know is which aspects of biology are contingent on the particulars of our bio-chemistry, and which are profound consequences of the logic of natural selection. This paper has attempted to add to the small, but growing number, of ALife studies which tackle the question of the division of labour and internal organisation. We have laid down ground work for a systematic investigation of the ultimate causes of the evolution of internal differentiation and organisation.

### Appendix A

We sketch the solution to the model via the replicator equation formalism, for the case of mixed strategies playing within variable levels of group structure.

Individuals have strategies which are specified via a probability  $p$ . They play strategy A with probability  $p$ , and therefore B with probability  $1 - p$ . An individual with strategy  $p$  who interacts with another individual with strategy  $q$  receives an expected payoff of:

$$F[p, q] = pqR + p(1 - q)S + (1 - p)qT + (1 - p)(1 - q)P \quad (12)$$

Selection acts on  $p$  and thus the population is specified by the function  $\rho(p)$  which is a 1D function which specifies the density of the population playing a strategy for every value of  $p \in [0, 1]$ . The systems dynamics are specified by the replicator equation:

$$\dot{\rho}(p) = \rho(p) (f(p) - \bar{f}(p)) \quad (13)$$

where  $f(p)$  is the fitness of the individuals for a given  $p$ , and  $\bar{f}(p)$  is the mean fitness of the population.

The fitness of any strategy comprises of two parts. The fitness gained in the group phase, and the fitness gained in the population phase. Call these fitness  $f_G$  and  $f_P$  respectively. In the absence of mutations strategies always play with like

strategies in the group phase, thus:

$$f_G = F[p, p] \quad (14)$$

in the population phase strategies play with every other strategy. The average payoff is given by the strategy they would have received from playing a hypothetical average individual. That is:

$$f_P = F[p, \bar{p}] \quad (15)$$

where  $\bar{p}$  is the average value of  $p$  in the population.

Total fitness is thus:

$$f(p) = T_G F[p, p] + T_P F[p, \bar{p}] \quad (16)$$

we normalise by saying that  $T_G + T_P = \tau$ , i.e. that the whole cycle happens over  $\tau$  units of time. Let  $\alpha = T_G/\tau$ . By dividing by  $\tau$  we arrive at:

$$f(p) = \alpha F[p, p] + (1 - \alpha) F[p, \bar{p}] \quad (17)$$

We thus have a fitness defined for every possible strategy, which can be used to model the situation by means of the replicator equation.

Population dynamics follow from numerical integration of equation 13.

### Abstract

A minimal artificial living cell is a sustainable and reproducible cell-like entity composed of biological components such as proteins, DNA, RNA and phospholipids (Luisi et al. (2006)). The most realistic strategy in producing such an artificial cell is assembling biomolecules that imitate the architecture and the function of biosystems in living organisms (Oberholzer et al. (1995)). Firstly we reconstructed the gene expression machinery with the minimal number of purified translation factors addressing the need for an artificial gene expression system. The PURE (Protein synthesis Using Recombinant Elements) system (Shimizu et al. (2001)), a key tool for bottom-up synthetic biology, enables information encoded in the DNA sequence to be converted to functional proteins and enzymes, and can be used in developing artificial cellular components. Another important and indispensable feature of artificial cells is the encapsulation of genetic information and gene expression system by a lipid bilayer membrane (Ishikawa et al. (2004); Kuruma et al. (2009)). This is also important to sustain an individual from environment. In addition to compartmentalization of biomolecule components, the membrane provides a structural platform for important biological functions such as selective transport of materials, adoption of environment information, production of energy, etc. Actually, many of the vital cell functions reside on the lipid membrane, and these functions mostly rely on membrane proteins.

In this paper, we focused on three important membrane functions, i.e. (i) lipid synthesis, (ii) energy production and (iii) membrane protein synthesis. All these membrane functions were indispensable for sustaining cell alive and must be reconstructed as a consequence of internal metabolic reactions. Each membrane function has the corresponding membrane proteins. Therefore our strategy is to construct the membrane function on artificial membrane vesicles, liposomes, through the gene expression of the corresponding protein components by the PURE system. (i) For the lipid synthesis, we selected eight membrane enzymes involving in the biosynthesis process of major phospholipids from a bacterial genome. These eight enzymes were synthesized by the PURE system in the presence of membrane fraction (membrane Nano-Disc) and measured their activities. The goal of this project is to develop a biochemical network *in vitro* that aims to produce several kinds of phospholipids necessary for the formation of cell envelop. As the first step, we have succeeded to synthesize two membrane enzymes inside liposomes and individually detected their activities (5). This result would be a fundamental for the construction of a self-reproducible cell mem-

brane. (ii) For energy production, a membrane embedded super molecule complex, FoF1-ATP synthase (FoF1), was synthesized through the eight kinds of component proteins. The function of FoF1 is to produce ATP molecules, which is an energy source of most cellular activities, based on the proton gradient across a membrane. We have succeeded to synthesize FoF1 complex by the PURE system and detected its ATP synthesis activity that driven by an artificially generated proton gradient. Furthermore, the reconstructed FoF1 is coupled with another membrane machinery, bacteriorhodopsin (bR), to construct an artificial organelle. The bR is proton pump machinery that transports protons to inside of the membrane vesicles due to light stimulation. Therefore, our idea is that if the bR and FoF1 were allocated on a same membrane vesicle, the resulting vesicle is able to generate ATP molecules by light irradiation (Fig. 1). In this design, we have succeeded to detect the production of ATP molecules in the rate of 35 nmol ATP/hr/mL Reaction Solution. If the produced ATP could be used for protein synthesis reaction within the PURE system, this represents an energetically independent system and becomes a practical platform of autonomous artificial cell. (iii) All these membrane machineries are built up based on a spontaneous membrane insertion of the synthesized membrane proteins. However, a certain kind of membrane protein cannot be integrated spontaneously. In that case, the membrane protein needs a help of special membrane machinery, Sec translocon, to achieve the native formation on a lipid membrane. The Sec translocon works as a gate to mediate a membrane insertion and secretion of membrane proteins (Fig. 2). Therefore our idea is to synthesize the component proteins of Sec translocon by the PURE system and construct the Sec translocon on membrane vesicles. Since most of membrane proteins are generated through Sec translocon in living cells, any types of membrane protein can be produced after the construction of Sec translocon. So far, we have succeeded to synthesize three component proteins (SecYEG) of Sec translocon of bacteria and to detect its heterotrimeric complex formation on a lipid membrane. Furthermore, so synthesized SecYEG enables to produce another membrane proteins that cannot be spontaneously integrated into the membrane. This result indicates that, by synthesizing the Sec translocon, other important membrane proteins (machineries) can be continuously produced on the artificial membrane vesicles. Using our *in vitro* gene expression system, cell membrane functions can be partially constructed on the artificial membrane vesicles. More importantly, these membrane functions were autonomously constructed just by adding of the corresponding DNAs. The ability of an artificial cell to au-

Figure 1: Artificial organelle consists of FoF1-ATP synthase and bacteriorhodopsin for production of ATP.

tonomously produce membrane protein machineries by its internal genetic/metabolic network is consistent with the theory of autopoiesis by Varela and Maturana (Varela et al. (1974)). This is adaptive and complements the definition of life, self-reproduction, which is based on gene replication. We believe that our cell-free approach will become a central device for the construction of artificial cell membranes and a breakthrough for the realization of artificial cells.

## Abstract

Bipedal hopping has evolved as a mode of terrestrial locomotion in relatively few mammalian species. Despite large differences in body size, habitat use, and having evolved independently, all species that use bipedal hopping have remarkably similar limb morphology and posture. In addition, these species all have relatively long tails, presumably to assist in maintaining stability. However, the evolution of this behavior, and specifically the role of the tail, is not well understood. In this paper, we explore the evolution of bipedal hopping in a simulated animat, using a relatively simple musculoskeletal model and a rigid-body physics simulation environment. Results indicate that characteristically different hopping gaits evolve with alterations to the morphology, including the structure and actuation of the tail. Many of the results are consistent with behaviors and morphologies observed in natural organisms. However, in some cases effective hopping evolved despite key differences from nature, potentially inspiring new design approaches in robotic and biomechanical systems.

## Introduction

Bipedal hopping has evolved in relatively few mammalian species, but apparently for different reasons. In small animals such as kangaroo rats (Figure 1), spring hares, and jerboas, hopping is primarily used as a predator escape mechanism (Biewener and Blickhan, 1988). In larger animals, such as kangaroos and wallabies, hopping offers an energy-efficient means of locomotion over long distances (Dawson and Taylor, 1973). Despite size differences, the overall morphologies of these animals are quite similar. Specifically, bipedal hoppers tend to have long tails and powerful hind legs, which perform the majority of work during locomotion.

Yet, the evolutionary origins of this behavior, as well as many related issues, remain obscure. Can bipedal hopping evolve only with this morphology, or is it coincidence that these various species exhibit similar body proportions? Which aspects of the morphology are essential to hopping? Do there exist other morphologies for which bipedal hopping would provide an effective means of locomotion? Not only can answering such questions inform biology, but a better understanding of the evolutionary history and mechanics

of hopping has application in biomechanics, robotics and the development of prosthetics. Unfortunately, the relatively small number of species that exhibit this behavior, as well as incomplete fossil records, make it difficult to address this problem through natural systems alone.

Computational evolution provides a means to explore the selective pressures that can lead to hopping, as well as morphological characteristics that sustain it over generations. Moreover, both the behavior and body can deviate from those occurring in nature, enabling the researcher to discover more general principles regarding these issues. A previous study into the evolution of hopping using a 2D musculoskeletal model found that both quadrupedal and bipedal hopping gaits are very sensitive to changes in morphology (Hase et al., 2004). However, such a model does not take into account many aspects of hopping, such as maintaining balance, that are essential in the physical world. Our work explores the evolution of hopping in 3D physics-based simulation environments. While our early studies, described here, rely on rigid-body physics environments, more complex musculoskeletal models have been developed (Gutmann et al., 2012) and will be integrated into our investigations as computational capacity permits.

In this paper, we focus on the role of the tail in the evolution of hopping behavior. The virtual animat model approximates muscles, joints, mass and torque, enabling us to evolve biologically plausible patterns of movement. Through a series of five evolutionary treatments, described

Figure 1: The kangaroo rat was selected as the base morphology for studying the evolution of bipedal hopping, due to its representative morphology and the availability of information on both the mechanics and dynamics of its behavior.

later, we investigate the effect of different initial (and evolvable) tail configurations on the evolution of effective hopping gaits. We initially start with a fixed morphology resembling a kangaroo rat, but restrictions on the morphology are loosened with each subsequent treatment.

The contributions of this paper are as follows. First, the proposed muscle model produces locomotion patterns similar to those of natural organisms and limits the output potential of each individual joint. This model is computationally less expensive than a musculoskeletal dynamics simulator, enabling the large number of evaluations necessary in evolutionary approaches. Second, the results demonstrate that a tail is essential to hopping, but that different configurations can lead to very different gaits, some closely resembling those of biological counterparts (namely kangaroo rats and wallabies), and others different from any known species. Third, while we observed a close coupling among tail movement and the oscillation frequency of leg joints, we discovered multiple combinations that produced effective bipedal hopping behavior. Finally, we were surprised that many evolved tails had relatively low mass, as it is hypothesized that a heavy tail helps maintain a high moment of inertia in animals, producing a more stable gait. This result might be due to our relatively simple model of the morphology (we plan to use more detailed musculoskeletal models in the future), but might also represent a combination of morphology and behavior that has application outside biology.

## Related Work

The role of the tail in locomotion is of considerable interest within biology. In their studies of geckos, which are not bipedal hoppers, Full and colleagues found that the tail is essential to both orientation control and gait stability (Jusufi et al., 2008; Libby et al., 2012). Alexander and Vernon studied the musculoskeletal system of kangaroos and described the overall mechanical system and the forces exerted during hopping (Alexander and Vernon, 1975). They also first hypothesized that the tail was necessary to balance the angular momentum produced by the swinging legs during hopping. However, to our knowledge no one has yet tested this hypothesis, nor explored its significance in other hopping species.

In robotics, hopping is an intriguing locomotion strategy for its potential energy efficiency and the ability to rapidly change elevation. The latter is particularly important to radio communication, as signal propagation distance is greatly increased by moving transmitters above ground level (Cintrón and Mutka, 2010). Indeed, research in this area has led to the development of small robots capable of both self stabilization and hopping (Zhao et al., 2009). Prior studies on hopping have also addressed mechanics of simple, single-joint actuated robots that were able to achieve stable hopping gaits (Berkemeier and Fearing, 1998), and single-hop robots have been constructed using pneumatic muscle actu-

ators (Niiyama et al., 2007). It has also been shown that combining several hops was more energy efficient than a single, powerful hop, while producing the same jumping height (Aguilar et al., 2012). This efficient hopping motion was discovered after analyzing thousands of results, lending support to harnessing the search capability of evolutionary computation in order to address similar problems.

Evolutionary approaches have been shown to be successful in many robotic and biological applications. Beginning with the foundational work of Brooks and Sims (Brooks, 1992; Sims, 1994), computational evolution has proven effective at producing a diverse range of behaviors. Examples include evolution of neural-based controllers (Cliff et al., 1993; Ijspeert, 2001, 2008) and locomotion strategies for real or simulated robots (Bongard, 2011; Clune et al., 2009; Gomez et al., 2008). Other studies have focused on optimizing morphological components, such as the caudal fin of a robotic fish (Clark et al., 2012) and flexible joints in terrestrial robots (Moore and McKinley, 2012). As noted earlier, the evolutionary computation study conducted by Hase et al. (Hase et al., 2004) found that 2D animats with simulated neuromuscular morphologies were capable of both bipedal and quadrupedal hopping motions similar to their respective biological counterparts. By applying evolutionary approaches to the study of bipedal hopping in 3D animats, we hope to gain insights into this behavior at a level not previously explored.

## Methods

We began our study with an animat based roughly on the morphology of a kangaroo rat, whose gaits have been analyzed extensively with the aid of high-speed, high-resolution video cameras (Gutmann et al., 2013); see Figure 2. We first evolved gaits for fixed morphologies, then allowed evolution of morphological parameters such as limb dimensions, joint output potential and mass distribution.

**Virtual Animat.** Figure 3 shows the initial animat constructed in the Open Dynamics Engine (Smith, 2012), with body part dimensions corresponding to that of the kangaroo rat. The animat also features a controller that actuates all joints. Kinematic data of the kangaroo rat's hopping gait indicated that the individual joints move in a periodic motion similar to a sine wave. Hence, for this initial study where we focus on steady state hopping gaits, a relatively simple sinusoidal controller was implemented; our ongoing investigations use more complex neural-based controllers. In addition, left/right symmetry was enforced. This decision was made primarily due to the difficulty in evolving a controller for a predefined morphology (unlike nature, where they evolved together). Preliminary experiments found that asymmetric controllers had difficulty achieving stable gaits due to large differences in the length of hind and fore limbs. Moreover, observation of kangaroo rats demonstrates left/right symmetry during hopping.

Figure 2: X-ray video progression of a kangaroo rat hopping across a force plate to quantify hopping dynamics.

**Muscle Model.** Animals exhibit fluid movements produced by muscles contracting and relaxing in a coordinated manner. To approximate such dynamics in a rigid-body simulator such as ODE, we modeled muscular connections using hinge joints with appropriate constraints. In particular, we devised a model in which the energy an individual joint can expend during actuation is limited. Doing so prevents situations in which a joint can move with an infinite amount of force, an impossibility in biological organisms. Figure 4 shows the range of motion and relative power of each joint in the morphology. Limiting the maximum force an individual joint can exert produces a system in which multiple joints must work together to move the animat. This muscular model is applied only to the rear legs, as the fore legs do not factor heavily into the locomotion pattern for evolved individuals.

We found that this model produced coordination among the components of the body and natural looking gaits. During locomotion, animal joints do not always move throughout their entire range of motion (for example, strides may be shortened to handle rough terrain, or the center of gravity may be lowered by crouching to improve balance). If the potential were unlimited, joints would always move throughout their full range of motion, irrespective of external forces. By limiting potential, the range of motion of one joint would be indirectly determined by the evolved muscle output parameters of other joints. Moreover, limiting the overall output potential of each joint allowed the limbs to flex and react to the ground when landing, increasing stability and the “naturalness” of the gait.

Figure 3: Initial simulated animat used in this study, with morphological dimensions and mass based on kangaroo rat.

Figure 4: Two-dimensional representation of the animat joints, with range of movement indicated.

**Evolutionary Setup.** For each of five treatments, described in the next section, we executed 25 replicate runs, each with a unique random number seed. In each run, a population of 150 individuals evolved for 4000 generations. Fitness was defined simply to be the distance traveled in 10 seconds of simulated time. No special selective pressure was applied to prefer hopping to other forms of locomotion. Successive generations were populated using 2-way tournament selection with mutation and crossover as defined below. The genome comprised 12, 14, or 16 values, depending on the treatment, as shown in Table 1. For treatments 1 and 2, the genome did not include parameters for an actuated tail.

The mutation rate was relatively high, 20%, but mutations were defined according to a gaussian distribution, so an individual mutation was unlikely to produce a large change in value. We found this approach to be effective given the control strategy used, where a large change in a single key parameter, such as a phase offset, often produced an unstable solution. A more conservative mutation approach allowed for gradual change to gait patterns over generations.

Single-point crossover was applied with a probability of 25% per genome. Crossover exhibited spatial locality, in that parents for an individual solution were chosen within a defined range. Specifically, we applied a geographical approach (Spector and Klein, 2006), where the population is considered as a one-dimensional line with wrap-around. Individuals are produced from parents that are considered to be close to their offspring.

Table 1: Individual Gene Limits

Parameter	Min. Value	Max Value
Actuation Freq.	0 Hz	2.5 Hz
Hip Orientation	0°	337.5°
Knee Orientation	0°	337.5°
Ankle Orientation	0°	337.5°
Toe Orientation	0°	337.5°
Shoulder Orientation	0°	337.5°
Elbow Orientation	0°	337.5°
Center of Mass	body center - $0.25 \times \text{length}$	body center + $0.25 \times \text{length}$
Hip Power	0 (passive)	1.0
Knee Power	0 (passive)	1.0
Ankle Power	0 (passive)	1.0
Toe Power	0 (passive)	1.0
Treatments 3, 4 and 5		
Tail Actuation Freq.	0 Hz	2.5 Hz
Tail Orientation	0°	337.5°
Treatment 5 Only		
Tail Length	$0.07 \times \text{body length}$	$2.2 \times \text{body length}$
Tail Mass	$3.25 \times 10^{-4} \times \text{body mass}$	$0.6 \times \text{body mass}$

## Experiments & Results

The 5 treatments, described below, investigate the role of the tail in bipedal hopping, including interaction with other aspects of the morphology and effect on gaits. To assist the reader in visualizing evolved behaviors, we have placed videos of selected evolved behaviors on a YouTube account:

Treatment 1: <http://y2u.be/V56Xmgf7pxE>

Treatment 2: <http://y2u.be/M1BWxwVUAEM>

Treatment 3: <http://y2u.be/bizIMorOv9g>

Treatment 4: <http://y2u.be/dIyoE0eMm2A>

Treatment 5: <http://y2u.be/OXIbXrwXU3Y>

**Treatment 1: No Tail.** In Treatment 1, individuals lack a tail. Most (18) of the 25 replicate runs failed to produce bipedal hopping, instead evolving *bounding* gaits, where fore and hind limbs alternate contact with the ground. Such gaits were common throughout the study, since they offer relatively stable locomotion, albeit slower than bipedal hopping. Six of the replicate runs were able to manage two or three hops before settling into a forward-leaning gait and then regressing to a bounding gait. However, in one run, the dominant individual, shown in Figure 5 and the Treatment 1 video, exhibited a fairly effective bipedal hopping gait, although it flipped over near the end of the simulation period. Presumably, the bounding gait was a more stable configuration for tailless animats. Examination of early generations found that many individuals attempting to hop tended to flip

over backwards, resulting in low fitness scores. One encouraging trend that emerged in this and subsequent treatments was the effectiveness of our muscle model in simulating flexible joints. During locomotion, joints flexed to react to contact with the ground, resembling the function of biological musculoskeletal systems.

**Treatment 2: Fixed, Rigid Tail.** In the second treatment, individuals had a fixed, rigid tail, and were able to evolve hopping gaits with relatively high fitness values. However, we observed that the majority of successful hoppers used the tail as a “kickstand” to prevent flipping over, as had occurred in Treatment 1. The increased stability enabled individuals to hop farther. The best evolved individual for this treatment can be seen in Figure 5. Most of the replicate runs produced individuals that used their tail in this manner through the entire simulation period, however, a few managed to execute two or three hops between tail taps. Although not ideal, this tail-tapping motion turned out to be an important aspect in the emergence of hopping gaits.

**Treatment 3: Actuated Tail.** The fixed tail in Treatment 2 approximates the initial posture of a kangaroo rat at the start of a hopping motion. In Treatment 3, we expanded the genome to allow the tail to evolve a speed of oscillation value as well as a starting position. We expected to see hopping gaits that did not use the tail as a kickstand as had occurred in Treatment 2. Evolved solutions for this treatment did tend to favor oscillating tails that counteracted the angular momentum of the body. However, the kickstand effect was still present in many individuals, although not as predominant as those evolved previously. In addition to the kickstand function of the tail, evolved individuals demonstrated a coupling between tail and leg oscillation that has the tail moving against the legs to limit the rotation of the body during the hop. An evolved individual for this treatment can be seen in Figure 6, which shows the use of the actuated tail to stabilize the body pitch.

**Treatment 4: Tail Collision Removal.** In a natural environment, hopping species tend not to drag their tails on the ground or even allow the tail to contact the ground at high speeds, in order to avoid injury. In Treatment 4, we explicitly removed the kickstand effect by simply preventing the tail from interacting with the ground. (Effectively, the tail could contact and penetrate the ground with no effect on the animat.) We expected solutions to instead use the tail as a counterbalance to angular momentum, consistent with a prevailing hypothesis in biology (Bartholomew and Caswell, 1951; Alexander and Vernon, 1975; Libby et al., 2012). Instead, the results from all replicate runs tended towards bounding gaits similar to those in Treatment 1. We suspect that the additional mass associated with a tail made it more difficult for the individuals to maintain balance, resulting in the tendency to lean forward.

Figure 5: Behavior of evolved tailless and fixed-tail individuals. The fixed tail individual was able to hop more effectively by using its tail as a stabilizer to prevent flipping over backwards.

Figure 6: An evolved hopping individual from Treatment 3 with an actuated tail. Note the coordination between tail and legs to maintain body pitch throughout the hopping motion. In the evolved individual from Treatment 5, the tail evolves to be shorter than those of the previous treatments, enabling faster hopping.

**Treatment 5: Evolvable Tail Morphology** In the first four treatments, tails appeared to be essential to maintaining stability. In biology, it is generally agreed that an important function of the tail is to counter the angular momentum of the body, discouraging body pitch changes over the hopping period (Bartholomew and Caswell, 1951; Libby et al., 2012). Since we had based the animat’s morphology on the kangaroo rat, we were curious what solutions would be discovered if tail length and tail mass were allowed to evolve. Indeed, Treatment 5 runs produced bipedal hoppers with tails approximately half as long as those in the earlier treatments; an example is shown in Figure 6.

**Performance Comparison.** Figure 7 plots the best and average fitness for each of the 5 treatments. In Treatment 1, solutions were forced to focus heavily on stable locomotion rather than maximizing the speed of movement, resulting in low fitness. Treatment 4 exhibited even worse performance

in both plots, demonstrating that in these experiments tail tapping is an important part of the behavior, at least as the animat starts moving. Treatment 5 had the best performing individuals across all treatments, although the average performance was similar to that of Treatment 3. This result is likely due to individuals that were unstable and attained low fitness scores. Individuals in Treatment 2 had the second best performance, presumably by using the tail to stabilize the animat during hopping. Treatment 2 also had the best average fitness, indicating that the static nature of the morphology likely made finding stable solutions easier.

**Analysis.** Considering the high performance achieved in Treatment 5, we sought to determine which factors and relationships gave rise to effective bipedal hopping. We discovered that in the top 10% of evolved solutions in this treatment, there existed a relatively tight coupling between tail and leg oscillation frequencies. Figure 8 presents these data

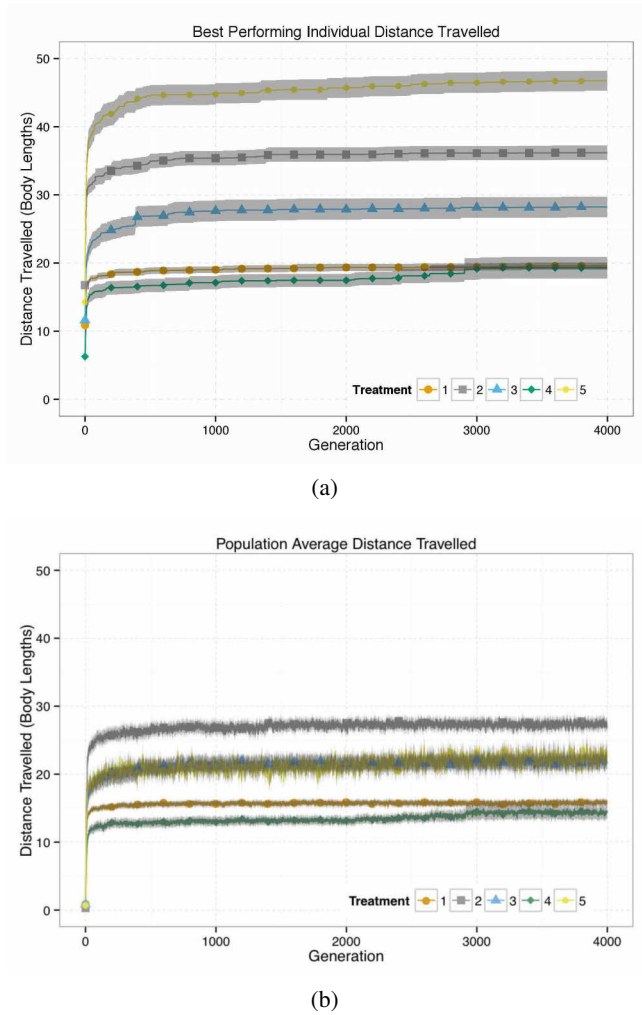

Figure 7: Fitness of 5 treatments over evolutionary time: (a) Best performing individual, averaged across 25 runs for each treatment; (b) Average performance in each evolved population, averaged across 25 runs for each treatment. Shaded bands indicate 95% confidence intervals.

for individuals in the final generation. In the figure, the tail oscillation frequencies are generally near either a harmonic of the leg oscillation frequency, or they act as a passively flexible joint (lower right). Results that fall on or near these harmonic values have tails that move directly opposite to the rotation of the body, apparently helping to maintain a more effective body orientation. In the solutions indicated as passively flexible, the tail oscillation frequencies are so low that they behave as a flexible joint that moves only in reaction to the hopping motion, thus countering rotational movement. The coordination in phase between tail and leg movement is essential for successful individuals and is supported by biological observation. In hopping species, tails tend to move in concert with the rest of the body producing a unified gait pattern. In our observations of evolved animats, individu-

als lacking this coordination tend to produce extraneous or detracting movements that actually hinder performance.

Figure 8: Relationship between the leg oscillation frequency and tail oscillation frequency in Treatment 5. The straight lines indicate harmonics between the two frequencies. Evolved solutions tended to either fall near these lines or in the passively flexible region.

A second area of interest is the evolved mass of the tails and the resulting moments of inertia. As seen in Figure 9, the evolved results tended towards tail masses that were less than 15% of the total body mass. Indeed, tails in some of the best performing individuals accounted for less than 5% of total body mass. These light tails resulted in relatively low moments of inertia, as seen in Figure 10. Lower moments of inertia in these individuals potentially allow the body to generally change pitch throughout the hopping motion rather than maintain a stable body orientation.

This result is intriguing because stable orientation in hopping species benefits from a *high* moment of inertia in tails (Usherwood and Hubel, 2012). Moreover, Figure 10 indicates that there is no direct relationship between the tail moment of inertia and leg oscillation frequency. A possible explanation is related to our evaluation period. While the insight into high moments of inertia for the tails is well understood, the biological observations leading to this conclusion generally focus on *steady-state* hopping. However, in our treatments, fitness evaluation begins at the start of the simulation period which includes the startup phase. Hence, individuals begin from a stationary starting position and must begin to hop before reaching their final steady state. The inclusion of the startup period places an emphasis on stability during the transition from stationary pose to hopping to avoid falling over or becoming unstable. This pressure

Figure 9: Relationship between the leg oscillation frequency and tail mass as a percentage of total body mass. Lighter tails are favored, although the evolved tail length remains relatively constant even for different masses.

Figure 10: Relationship between the leg oscillation frequency and moment of inertia for an individual. A low moment of inertia generally means the animat is likely to change body pitch during hopping.

likely forces the solutions to evolve parameters that encourage stable startup gaits over those that are most efficient or fastest during the steady-state phase. One possible approach is to delay the evaluation until the animat has had an opportunity to start moving. Adding such a transient phase, which has proven successful in other recent studies (Moore et al., 2013), may encourage tail parameter evolution towards steady state hopping. However, we note that at the time of this writing, a preliminary set of experiments showed that a transient phase actually *reduced* fitness. This issue is a topic of our ongoing research.

## Conclusions

Although relatively uncommon in the animal kingdom, bipedal hopping provides benefits both for energy efficiency and as a survival mechanism. A better understanding of this behavior, and how it evolved, not only informs biology but has implications for the design of robotic systems. We have developed a computationally-efficient kinematic model that approximates the function of natural muscles and is suitable for integration into evolutionary algorithms. In 5 treatments, we explored the role of the tail in hopping gaits. We found that a tail is essential to hopping, as tailless individuals resorted to bounding or shuffling gaits. Evolved gaits exhibit similarities to their biological counterparts in terms of tail movement and joint coordination. However, our results also show that bipedal hopping is not limited to the morphological configurations observed in nature, but can evolve in other morphologies (i.e., those with short, light tails). Indeed, the initial morphology based on the kangaroo rat dimensions proved not to be the most effective morphology. Finally, the inclusion of the startup phase in fitness evaluation led to an alternate use for the tail as a stabilizer, which to our knowledge has not been previously reported.

In future work we plan to conduct more in-depth study of transient versus steady-state hopping behaviors and the pressures influencing them. We also plan to refine our simulated muscular model to more accurately capture the behavior of natural muscle and tendon systems. Finally, as with our studies of aquatic robots, we intend to evolve more complex controllers, using artificial neural networks, for bipedal hoppers.

## Abstract

In this paper is investigated the problem of managing limited resources in human-robot interaction with a computational architecture of emotion. The architecture is based on the appraisal theory of affect and an ethological motivational model of task selection. Key variables and performance criteria for robotic energy autonomous behaviour in interaction with humans are discussed. The role of arousal for modulating effort of movement is explored. It is shown that the architecture can manage task selection and the effort of the movement and offers sustainable basic-cycles in exemplar “two-resource problem” test-bed scenarios for an iCub robot. An extension of the architecture with a third ‘resource’ – safety – is presented and how the architecture is able to solve the new ‘three-resource’ problem is demonstrated.

## Introduction

Research on robots interacting with humans perennially arouses interest. There are many research agendas focused on human-robot interaction (HRI), for example, concerning service robots for helping the elderly or disabled people, robot toys for treatment of autism in children, artificial pets for entertainment, autonomous vehicles and robotized spacesuits. The requisite artificial agents should be able, autonomously, to balance their internal needs such as energy homeostasis, hardware integrity, temperature balance, and at the same time fulfil designer requirements whilst interacting efficiently with the human inter-actor. If a certain degree of autonomy is missing and there is no remote control operation, the agent will require a predesigned action set for every possible environment state, an impossible feat in a complex environment where humans reside.

McFarland suggests that at the root of autonomous control is energy autonomy (McFarland & Spier, 1997; McFarland, 2008). The robot should be able to produce high work quality whilst efficiently utilizing the available energy level of its batteries. Furthermore, the autonomous robot must find the behavioral trade-off between re-charging and working. Managing these two conflicting requirements fundamentally, constitutes the “two-resource problem”, which has become a test bed for several studies in autonomous robotics (Avila-García & Cañamero, 2004; Lowe et al., 2010). The main emphases of the proposed solutions are: firstly, the amount of time the robot should spend at each resource, and secondly, the time at which (work, fuelling) behavioural activities should be switched (sequencing of behaviors) (Wawerla & Vaughan, 2009). Effort during movement is another crucial factor regarding energy autonomy. Responding to urgent situations such as items falling from surfaces, fire hazards,

boiling, or/and overflowing, water requires fast and effortful action. However, in moments of relative calm, the autonomous robot should conserve its energy and, essentially, ‘take it easy’. More effortful movements could raise the safety hazard and this is another reason that the robot should “spare its effort” in situations other than those requiring urgency.

For the purpose of addressing the above considerations for robot autonomy we have developed an affective-cognitive architecture. This combines ‘top-down’ processes, enabling (human-like) expression of emotional state, with ‘bottom up’ processes grounded in the energy balancing mechanisms of the robot. We postulate that this hybrid approach offers the robot greater potential for flexibility when performing tasks that require the cycling of two or more activities. In (Kiryazov, Lowe, Becker-Asano, & Ziemke, 2011) a similar architecture was presented but implemented in a simulated NAO robot. Robot ‘work’ concerned an abstract behavioural sequence of reaching and then stepping onto a certain square on the ground. In the current set of experiments the work is less abstract and represents a more realistic service robot task subcomponent – robot tracking/monitoring of human action. The robot is required to track a ball, which the human inter-actor holds and moves. Specifically, the robot is required to uncover an interactive dynamic in relation to its energetic and movement capabilities guiding viable task (ball tracking, (re)charging) switching behaviour. This is further constrained by a requirement to interact ‘safely’.

The rest of the paper breaks down into the following sections: 2) The two-resource problem and humanoid service robotics – we provide a description of a general two-resource framework for autonomous robots and its adaptation to the proposed service robotics specific requirements; 3) An affective embodied architecture – presenting a cognitive architecture for solving the specified problems; 4) Methodology; 5) Results; 6) Discussion – a summary of present work and insights, and proposed future experiments using the cognitive architecture incorporating emotional expression and recognition mechanisms; 7) Conclusion.

## The two-resource problem and humanoid service robotics

Two-resource problem scenarios offer a common test bed for studying behaviour cycling of autonomous robots under resource constraints. The two-resource problem requires an agent to maintain the level of two basic internal variables in relation to relevant environmental resources. In order for the problem not to be trivial, the robot behaviour that leads to an

increasing satisfaction of one resource-related variable should, most of the time, lead to the inability to satisfy the other resource-related variable(s). In such a framework one of the main problems is the choice of the best action for collecting the right resource at the right moment in time (Wawerla & Vaughan, 2009). The way of gathering a resource is also important as it is stated in (Spier & McFarland, 1986) it is not only important “what to do next” but also “how to do it”. When the two resources are the work and energy, which a mechanical robot should balance, then the choice of an effort of a movement (speed, stiffness) contribute importantly to this two-resource problem.

In the two-resource problem framework of McFarland and Spiers (McFarland & Spier, 1997) the artificial agent (animat) is represented as a state space. The animat is characterized with a minimum set of state variables that are sufficient to describe its psychological state. The animat should maintain homeostasis of this state (not going into a lethal limit), handling the perturbations caused by its actions and the environment. Within this framework, McFarland and Spiers’ experiment with different decision strategies for the animat. They show that very simple cueXdeficit motivation leads to good performance in a lot of different environments. The motivation of a robot/animat to approach a particular resource ( $r$ ) is calculated as:

$$M_r = D_r \times C_r \times K_r \quad (1)$$

where  $D_r$  is the deficit of the resource-related variable in relation to a homeostatic value set by the designer.  $C_r$  is the cue of resource  $r$  and represents its ease of access, e.g. for a mechanical robot a metric for the cue could be the euclidean distance of the resource of the current position of the robot. If a resource is temporarily not visible, instead of having a zero cue value (cf. (Spier & McFarland, 1996)), it is proposed to assign a low fixed value to the cue – the so-called “ambient cue”. This represent “the knowledge” of the agent that there should be some of this resource somewhere in the environment and could motivate the agent to search for it if this resource deficit is very low (even if the agent cannot see it). When the motivation is dependent on the cue, two types of behavioural patterns – opportunism and persistence – emerge, which are important for behavioural stability in two-resource problem frameworks (Avila-García & Cañamero, 2004; Spier & McFarland, 1996).  $K_r$  is the availability of tools in the environment, which are required to handle resource  $r$ . The cue of a resource is based on sensor input and the deficit is measured through proprioception. This model captures animal behaviour at an abstract level where a basic requirement of populations of animals is to choose between food and water resources (Sibly, 1975). For animals the most important resources are food and water or, alternatively, fuel and mating. The work and energy are suggested as robotic analogues for the two basic resources (McFarland & Spier, 1997).

A basic measure for behavioural stability for a robot in such two-resource problem scenarios proposed in the above-mentioned studies is the ability of the system to produce sustainable basic cycles – cycles in the state space of the robot which don’t cross the designer-specified “lethal” limits of the resource-related variables.

Figure 1. Left: A typical two-resource problem in a 2D world where the robot collects multiple resources of two different types (e.g. blue = water, red = food). Right: A two resource problem for service humanoid robots, where there is one fixed energy resource and a dynamic “work” resource.

For a simple wheeled robot the movement towards a resource and its effort is simply controllable by the speed of the two motors for the left and right wheel. Humanoid robots have many more degrees of freedom and the actions they perform are much more complex. In order to simplify the optimization problem for such robots an algorithmic distinction between the task switching mechanism and the effort of movement is reasonable. In order to translate simple wheeled robot two-resource problems to humanoid robot and service robotics scenarios certain factors should be considered. In common, there is only one “energy resource” and that is a charger, which may be in a fixed position the location of which is knowable regardless of the robot’s current position. However, “work” – which is often related to human behavior, entails complex environmental and social dynamics where interaction with human decision making is concerned. At any time the robot should choose the most appropriate action – for work or charging. The actions can be performed at different speeds or degrees of stiffness of the actuators, the latter relating to precision of performance, safety and energy efficiency.

Robots can have different profiles of energy consumption related to their speed of movement. If movements at low speed are more energy efficient, then the robot has to choose the speed apt to solve the trade-off between energy and work efficiency. If the robot consumes less energy for higher movement speed, then the robot basically should move at the highest possible speed for optimal behaviour. However, as previously suggested, higher speed could raise difficulties in HRI, e.g. decreased safety.

Safety is an important aspect related to effort of movement in HRI. Higher speed or more power in the actuators will also mean a greater safety hazard in a close human-robot interaction. Safety could be defined as a third resource, in the same framework, which the robot should maintain within appropriate limits in order to be efficient. One way the robot could gather “safety” is to completely stop when the safety hazard assessment is too high (for example, a human is nearby and the robot is moving fast). Another more relaxed way is to reduce speed and stiffness of the motors.

Generally, emotion plays an important role for efficient communication (Thill & Lowe, 2012), (Bar-On & Parker, 2000). Expressing emotion states could provide fast feedback to another humanoid with respect to the current mental state of the partner in a cooperative task and potentially enhance the human-robot interaction. For safety purposes, it is very important that the robot recognizes human intention and action in order to act appropriately. On the other hand, the robot should meaningfully express its intention.

## An affective embodied architecture

The basic schema of the proposed architecture is shown in Figure 2. Part of the architecture is based on WASABI (Becker-Asano, 2008), which is a psychologically plausible appraisal theoretic model that has been successfully implemented and tested in the context of the virtual human MAX, who served as a museum guide and a card game player (Becker-Asano, 2008). In our architecture the unconscious appraisal process of WASABI and emotion dynamics in PAD space are used mainly. The task switching module substitutes for the BDI decision-making module of WASABI with the *cueXdeficit* action selection strategy.

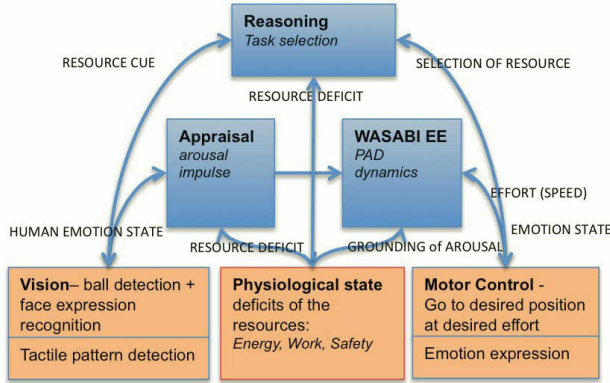

Figure 2. Basic modules of the architecture: modules depicted in orange boxes are robot specific. The other three (in blue) are implementation independent.

A brief description of the components of the architecture, which are relevant to the provided experimental results, follows below. Some of the modules, which are important for emotional communication with human (face expression, face expression recognition, tactile pattern detection), are not relevant for the presented results. However, we envisage their deployment in for future test scenarios. Their role for the efficient management of the resources and possible future experiments are proposed in the discussion section.

### Task switching

The task-switching module uses *cueXdeficit* action selection mechanisms (based on the model of McFarland and Spiers (Mcfarland & Spier, 1997)). The robot chooses an action of accessing a resource depending on which of the resources the robot has higher motivation for. This can be described by the following rule:

Gather resource  $k$ : if  $M_k = \max_i M_i$ , where  $M_i$  is the motivation for choosing a particular resource  $i$ :

$$M_i = C_i \times D_i, \quad (2)$$

$C_i$  – is the cue of the  $i$ -th resource and is provided by the vision module.

$D_i$  – is the deficit of the  $i$ -th resource. It is provided by the physiology module. In addition to the natural physiology measure of the energy level it also includes the other resources – work and safety – which are dependent on the

designer's goal. In this way the robot interprets the social environment in the same way as the physical one as suggested in (Dautenhahn, Ogden, & Quick, 2002)

### Appraisal

The appraisal process is controlled by generating and sending to the WASABI engine emotion impulses in the form:

$$Impulse = K \sum_{i=all\ resources} D_i^2 \quad (3)$$

where  $K$  is a coefficient tuned experimentally according to the dynamics of the Emotion Engine in such a way that the level of arousal during a run of the system could take all of the values from its minimum to maximum value (not remaining at the same level all of the time).

The emotion impulse equations represent general principles of unconscious appraisal in WASABI – that the impulses sent to the emotion engine should represent bipolar evaluations of the environmental state. In the current variant we only use the arousal dimension and negative impulses. From another side, the proposed impulse equation represents the cost function provided in (Mcfarland & Spier, 1997), which is a general criterion for deviation of the animat's equilibrium point in its state space.

### WASABI emotion engine

In WASABI the emotions are represented in the three-dimensional space of pleasure, arousal, and dominance by points with activation and saturation thresholds. The space itself is commonly referred to as PAD space.

The emotional state is a point in this 3D space and has internal dynamics, which is modulated by emotion impulses and other modules in WASABI. In the work presented here, the architecture uses only the arousal dimension. The WASABI engine modulates the execution of the task in the control module. The speed of each movement is made proportional to the current arousal level. A Similar relation between speed and arousal is shown in (Paterson, 2002) where the correlation between the perception of a character's arousal and its speed of movement is studied. WASABI engine also engages face expressions, which are not used in the results but discussed in the last section.

### Vision

The vision module evaluates the cues of the resources based on the perception capabilities of the specific robotic implementation. For the current version cues of energy resource (charger) and work resource (a moving ball) are:

$$C_{work} = \frac{MaxDistanceToWork - distanceToWork}{MaxDistanceToWork} \quad (4)$$

$$C_{energy} = \frac{MaxDistanceToCharger - distanceToCharger}{MaxDistanceToCharger} \quad (5)$$

In this way both cues' values are normalized in the interval [0,1]. As the safety is a special resource without a specific environmental cue representing it, its cue is set to the highest value of 1 all the time. This is also validated from the fact that

gathering this resource – stopping completely – could be achieved at any time immediately.

### Physiological state

The module calculates the resources' deficits based on introspection – monitoring internal physical properties such as electrical currents or more “abstract” deficits such as work and safety, which depend on the designer's requirements.

### Control

This module executes action for gathering the resource whose motivation is the highest, as provided by the task selection module. The action parameters, e.g. for effort of movement, are modulated by the emotion state in the WASABI engine.

The action for the work and charger resources consists of moving the robot's hand towards their position. Safety is “gathered” by stopping at a place for a certain period. The speed of the movement is proportional to the arousal level scaled in such a way that the resultant speed remains within appropriate limits (not too high: undesirable for the real robot because of possible damage; not too low: prohibitively slow for HRI).

## Methodology

For the specific tests of the proposed architecture we are using a scenario where a humanoid robot should follow a ball that is held, in front of it, at random positions by a human. When the robot moves it loses energy and in order to regain it, it should move its hand to a certain “resting” position. This scenario can be viewed as a minimalist analogy to a service robot having to refuel but also carry out a task that involves unpredictable dynamics. This work may also be viewed as a fundamental requirement of robot interaction with a human, i.e. that has some ability to dynamically track the activity of the human. The robot should cycle efficiently between working and refuelling activities in order to remain viable, i.e. not run out of energy, work and safety. The complexity of the task in this case is mainly caused by the “unpredictable” human behaviour – providing complex patterns of the ball (work resource) movement.

The lethal limits for the energy requirements of the robot are obvious – it should never go beyond a (lower) limit of a completely exhausted battery at which the robot stops moving and requires human intervention. In another, not so minimalistic, variant a higher “hibernation” threshold could be implemented which allows the robot to finish what it is currently doing and to find a safe location to ‘sleep’. This hibernation threshold can be manipulated from another “hibernate” behaviour. In the current experiments with the simulated iCub we use energy consumption proportional to the speed of movement. This is the simplest approximation to the real data, which we have collected with the real iCub. With such energy consumption dynamics, higher speed of movement is both more energy- and work-efficient.

The work limits are not obvious as the robot work requirements depend on the goals of the designer (Spier & McFarland, 1986). In the investigation presented in this paper, we use a convenient and natural measurement for the deficit of the work resource – a linear work production decrease from

the time point at which the work is “sensed” (the robot is aware of work to be done but cannot presently do it) and increase when it is actually working. In this way the work resource obtains constrained cyclical continuous dynamics similar to a physical resource. Here this is done more naturally than in (McFarland & Spier, 1997) where the robot should “pay” for energy when charging with its work points.

In order to define the safety resource dynamics we first define:

$$\text{Safety Hazard} = \text{Speed} \times \text{Human proximity} \quad (6)$$

The proportionality of safety to human distance is used in almost every measurement for safety hazards (Calinon, Sardellitti, & Caldwell, 2010; Kulić, 2006). The speed of the robot is a main factor for determining the force in an eventual collision so it is also of crucial importance for defining safety hazard (Kulić, 2006).

Any time the robot moves, it starts to decrease its safety variable level with the current level of safety hazard. When the robot stops at the charger or because it decided to “gather safety” the safety resource increases in the same constant linear fashion as the work resource. The latter two aspects of the safety dynamics were added mainly in order to obtain the same continuous and cyclical dynamics as the other two resources. More reasonable is that safety just equals the safety hazard. This is planned in the further development of the architecture where safety gathering could also relate to continuously decreasing of speed rather than a complete stop as in the current version. Another possible option of safe gathering behaviour could be the manipulation of joint stiffness, for example, decreasing the stiffness when the safety resource motivation becomes dominant. This will also make the change of safety hazard continuous with naturally constrained upper and lower levels.

In the so proposed three-resource problem the choice of right speed of movement is of crucial importance. High speed will decrease the safety. A slowly moving robot, however, will require more time to reach the ball and will reduce the amount of gathered work. A flexible mechanism is required to choose the proper speed at the right time. We suggest the arousal mechanism of our architecture is a suitable modulator of the movement speed for solving the three resource problem and produce sustainable basic cycles.

We are primarily interested in the three-resource problem that consists of managing variables for fuel, work and safety needs. However, the proposed architecture, as a basic requirement, should be able to handle the two-resource problem – produce stable basic behavioral activity cycles. Therefore, we first evaluate whether the cueXdeficit strategy is still applicable in the new setup and explore the role of arousal for modulating the robot's behaviour.

In a second experiment we use safety as a third resource and evaluate whether the architecture can maintain sustainable basic cycles in this three-resource problem. Although, as pointed out before, the safety hazard is defined as a reasonable measure the lethal limits of this resource are arbitrarily chosen. To demonstrate that such eventual behavioural stability is not trivial (the safety resource could be depleted in some of the environments) we will compare the performance of two variants of the architecture:

1. With three resources (work, energy, safety) and
2. With only two – resources (work, energy).

In the latter case we still use the same measure for the safety deficit but the architecture is “blind” for this “safety” resource. Although it can never take the decision to “gather safety” it could still “survive” in this case as the robot stops at the charger and also could stop for a shorter period when it is working (the ball is moving slowly). We predict that even if the robot dies in some of the environments in the “two-resource” variant, it can still be viable in the “three-resource” variant – so the average life-time of the “three-resource” robot-architecture system will be longer.

If there are only two resources, for the current robot energy consumption dynamics, the robot should go as fast as possible so the arousal mechanism is not so important. When the safety as third resource is announced that makes the problem of right speed non trivial because higher speed will increase the safety deficit. It is worth checking, however, whether the robot moving at the highest possible speed can still provide a solution for the three resource problem.

The experiments are performed using 21 runs for each of the two variants of the two architectures in 3 environments (therefore, 7 runs for each environment) for 35000 program cycles (approximately 15 minutes for each run). The detailed description of the used environments is summarized in the annex (table 2). In all environments the ball is moving with a sinusoidal speed on a line in front of the robot. In regular time intervals it disappears. The varied parameters are *the speed of movement of the ball* and *the time it is hidden* which are the key factors for environmental complexity. Higher speed of ball movement will require the robot to move more often and at a higher speed so that it will lose more energy and safety. If the ball is visible for a longer period, that will eventually decrease the work deficit if the robot is not succeeding to track it. The continuous pattern of movement is mainly chosen for implementation reasons – the vision module recognizes the ball much more easily when the ball’s position change is continuous with time (without sudden jumps), which actually should be the case if a human moves it. Although this simulated deterministic environment could look different to the unpredictable human behaviour it still has enough complexity, which for a simple reactive robot is not trivial. Extra complexity comes from the noise of vision and control modules.

For measuring the agent viability, we use two of the proposed viability indicators in (Avila-García & Cañamero, 2004) – life span and overall comfort:

$$LifeSpan = t_{life}/t_{run} \quad (6)$$

where  $t_{life}$  is the number of steps when the robot is viable,  $t_{run}$  is the maximum number of steps of one run

$$OverallComfort = \sum_{i=1}^{t_{life}} (1 - \bar{d}_i) / t_{life} \quad (7)$$

where  $\bar{d}_i$  is the mean of the deficit of all resources

The particular robotic implementation used for the experiments here uses the iCub robot (Sandini, Metta, and Vernon 2007). Most of the data presented here is collected in the iCub simulator. Some demonstrative results with the real robot are shown in the discussion section. For emotion recognition with the simulated robot the video stream of the web-camera instead of the cameras in the eyes of the

simulated iCub is sent to the face emotion expression recognition module.

Figure 3 An iCub robot following a red ball – real (left) and simulated (right).

The distance to the work and energy resource is calculated by using the Euclidian distance from the current hand position to the ball and the charger position. There is not any particular physical object representing “the charger” but we assume that the agent knows its state through proprioception.

The following modules from the iCub repository are used for the particular implementation of the vision, physiology and the control modules of the architecture:

- pf3dtracker – detects a single coloured ball and returns its coordinates in a 3D robot-centric reference frame
- ICartesianControl – moves the hand to a desired position for a desired time
- controlBoardDumper – logs the current consumption of the individual motors. Each value is time stamped, so the user can process them offline to compute the instantaneous power consumption
- emotion interface – controls patterns of LED on the face of the robot producing human-like facial expressions.

The last two modules are available only for the real robot and are not relevant for the following results with the simulated robot.

## Results

### Experiment 1: Arousal & the two-resource problem

The robot-architecture system ‘survived’ all the trials – it didn’t cross the lethal limits during the runs in this particular set of environments. That shows that cueXdeficit strategy is still viable strategy in our two-resource problem framework. In order to explore the role of the arousal mechanism we compare one of the runs in a more challenging environment (where the ball is shown for a longer period of time – environment 3 – see annex) and one in the least challenging (environment 1 – see annex).

Figure 4. Arousal level of the robot in an “easy” environment – (green) and a “hard” (red). The time is program cycles.

Figure 5. Basic cycles of a robot in an “easy” environment (green) and a “hard” one (red). The axes are also the lethal limits lines for the energy and work resources.

We can see that in the ‘easy’ environment arousal remains relatively low and the corresponding basic cycles are further from the lethal limits than in the more challenging environment where greater arousal is needed to produce behavioural stability.

Figure 6. Dynamics of some of the essential variables in a short time window of a run of the architecture in environment 3.

It is interesting to question why the robot doesn’t go into ‘over-opportunism’ (consuming a resource until it dies from the deficit of another resource) in this scenario where the consuming of the resources doesn’t deplete as in ethological experiments with wheeled robots. If a resource is not disappearing, that makes its cue value in the moment of gathering the highest possible value and an agent using a cueXdeficit strategy could become almost blind to the rising

of the deficit of the other resource. But as one can see in Figure 6 the robot still chooses to charge although the ball is present and very close to the hand if the energy deficit becomes considerably higher than the work deficit. One of the factors facilitating this is that the highest received cue value of the work is not maximum (at 1) but a little bit lower which is a side effect of the particular “embodiment” of the architecture (control module accuracy parameters and the dynamics of the tracking motion process). The periods with fixed cue of 0.2 (the ambient cue level) is when the ball disappears. In our scenario the ambient cue could be of benefit in the periods when the ball is missing for a certain short period but there is very high work deficit. In this case, the robot could still stay nearby “waiting” instead of starting to go to the charger. Although the robot is not over-opportunistic it still shows opportunism and persistence - it doesn’t switch to collect the other resource immediately as the deficit drops lower.

## Experiment 2: Safety & the three-resource problem

Firstly, we tested the three-resource variant of the architecture without arousal mechanisms but moving at highest possible speed. The architecture still survived the easy environment (1) but died in all the trials in the harder environments (2 and 3). Secondly, we performed tests with the proposed arousal mechanisms for modulating the speed. The basic cycles in the 3D space of the three resources’ deficit for one of the “viable” runs of the 3-resource architecture are shown in Figure 7. One can observe the cycle’s sustainability – the robot is not crossing any of the three lethal limits planes.

Figure 7. State space trajectory of a run of the “3 resource” system. The three planes 0 values provide lethal limits.

A comparison of the viability indicators of the “two resource” and “three resource” architecture is shown in Figure 8.

Figure 8. Viability indicators for the architecture with or without safety as the third resource. The graphs show the mean value of all (21) runs and standard error of the mean.

We performed one-tailed t-test in order to compare the life span in the two conditions (as we had hypothesized better performance in the three resource variant) and a two-tailed t-test for the overall comfort. There is no significant difference in the overall comfort -  $p = 0.26765$ . The life span however is significantly different at the 0.01 level of significance ( $p = 0.000235$ ). This result shows that the proposed 3-resource problem is not trivial (the robot dies before the end of the trial in the 2 resource case in 6 of the runs crossing its safety lethal limit) and succeeds in adapting (prolonging its life-time) when the architecture is extended for handling the three resources.

In Figure 9 the average deficit of safety is plotted. A one-tailed t-test for the mean safety shows the three-resource runs' safety significantly increases at the 0.01 level of significance ( $p = 0.000539$ ). This combined with the fact that overall comfort remains relatively the same shows that generally the new architecture compensates the pressure of having a new resource to handle with lowering the efficiency of gathering the other two resources – work and energy.

Figure 9. Average safety deficits with standard error for all the test cases

## Discussion

One possible criticism about the presented results with safety is that having such a flexible decision strategy regarding safety is not an appropriate way to deal with such an important issue as safe HRI. Usually industrial robots are programmed to completely stop whenever a human is detected in their workspace. That is a reasonable for robots with rigid bodies, big mass and high speed of movement because danger of injury in any collision between robots and humans is too big and should be avoided at any price. This is not the case however when the robots are “soft”. For example iCub has ImpedanceControl mode, which can be run parallel with CartesianControl. In this mode robot react to any external force and this could dampen a collision with human. The current version of iCub is still made of rigid material but future service robots could be made of soft materials so any possible collision with humans will not be damaging because of the soft robot body. When the robots have such “soft” properties the collision with humans is not something which should be avoided at any cost but could still be an unpleasant experience. Therefore, it could be flexibly balanced with the other requirements such as work and energy efficiency.

One of the main differences of our arousal mechanism with the hormone mechanism used in the competitive two-resource problem in (Avila-García, 2004) is the “inertial” dynamics of

arousal in connection with environmental changes. WASABI engine has its “internal inertia” – the arousing events need little time before the arousal becomes high and more time to cool down. The advantage of this inertia has not been demonstrated here but this could be done in experiments when the “dangerous” (arousal causing) event are not uniformly distributed but are grouped in time. Another advantage of such a property is that it is closer to the arousal dynamics in the biological systems.

There are several studies showing that other people’s emotional states tend to induce similar ones in human interactors (Hatfield, Cacioppo, & Rapson, 1994). A more aroused human when the robot is moving faster and calmer when there is no urgency would tend to increase safety within the interaction. Further experiments, however, with human participants and iCub are needed to validate that assumption. In order to express robots’ emotional states three different sets of LED face patterns corresponding to the current level of arousal are used. In (Paterson, 2002) it is shown that people assess the level of arousal based on the corresponding speed of movement. The emotion expression of the real iCub serves as extra emotional feedback.

From another angle, recognizing the emotional state of the human in a cooperative task could also be of crucial importance. Human arousal could be a fast heuristic of anticipated danger. A robot could detect the arousal and adopt its behaviour appropriately before the human becomes aware of the anticipating event (Rani et al., 2004). Multimodal emotion expression recognition based on the face expression recognition module and touch pattern classification is being developed. The system can distinguish two-different types of facial expressions and three touch patterns in real time. Future experiments are planned which will prove the role of human emotion state recognition benefits for resource managing in HRI.

## Conclusion

In this paper a particular two- and three-resource problem setup for humanoid robots in a scenario suitable for service robotics tasks is reported. In addition to that mainly exploited in other similar studies – task switching – the concept of ‘effort’ is emphasized here, which is essential for two-resource problems and is studied separately from the action selection. A bio-inspired affective architecture, for solving the multiple resource problems, is presented. We show that the proposed architecture preforms stable basic cycles – a measure for behaviour stability for two-resource (work, energy) problem. The role of ‘safety’ as a necessary third importance resource in HRI is presented. The safety and work efficiency although being high-level entities dependent on designer requirements are successfully incorporated in the architecture in the same way as a physically constrained resource such as the battery energy level. We show that with a reasonable safety measure the architecture can handle the three-resource problem. The arousal, used for maintaining the right effort of movement, is an important modulator of the cueXdeficit action selection mechanisms in the two and three resource problems.

## Annex 1

The main parameters of the architecture for the presented results are summarize in the table below:

Table 1 architecture parameters

Parameter	Value
Maximum of work	1770
Maximum of energy	1
Maximum of safety	470
Distance to the ball when “work is consumed”	0.11 m
Time of standing still when “safety is consumed”	3.5 sec
Ambient work cue value	0.2

Ball position is controlled by equations of time shown below. Coordinates of points are in robot-centric coordinate system with a centre on the floor below the legs of the robot. The ball is hidden in regular time patterns in order for the environment to not be too hard to live in.

Table 2 Environment properties (ball movement patterns)

Environment index	Ball movement pattern
1	Ball position = $A + (\cos(t/4)/2 + \frac{1}{2}) * B$ t- current time in seconds A (0,1,0.3), B (0,0.87,0.4) Ball is hidden every 50 sec for 50 sec
2	Ball position = $A + (\cos(t/3.5)/2 + \frac{1}{2}) * B$ t- current time in seconds A (0,1,0.3), B (0,0.87,0.4) Ball is hidden every 50 sec for 50 sec
3	Ball position = $A + (\cos(t/4)/2 + \frac{1}{2}) * B$ t- current time in seconds A (0,1,0.3), B (0,0.87,0.4) Ball is hidden every 60 sec for 40 sec

# Simulating Sleeping Sickness: a two host agent-based model

Simon Alderton, Dr. Jason Noble & Prof. Peter Atkinson

Institute for Complex Systems Simulation  
University of Southampton  
simon.alderton@soton.ac.uk

## Abstract

Agent-based modelling is useful for policy evaluation in fields such as epidemiology. The current paper presents a model of Human African Trypanosomiasis (HAT), or sleeping sickness: a disease which is becoming increasingly prominent due to recent epidemics. Associated medication is often scarce, whilst diagnosis through blood screening is not always effective. Current modelling methodology uses simple reaction-diffusion models to predict future epidemics, but this makes policy at the village level difficult to evaluate. Agent-based, object-oriented simulation provides a simple means of adding complexity to models of sleeping sickness, allowing the easy incorporation of spatial and vector data. We present an exploratory two-host agent-based simulation for humans and cattle, applying known values for sleeping sickness infection rate, before evaluating the model's policy implications and suggesting steps for future improvement.

## Introduction

Agent-based modelling (ABM) in artificial life has long been used to examine fundamental questions in areas such as the evolution of cooperation or communication. However, ABMs have also been used in a pragmatic way in disciplines such as anthropology (e.g. Gumerman et al., 2003; Lansing and Kremer, 1993), conservation biology (e.g. Watkins et al., 2011), and epidemiology (e.g. Muller et al., 2004; Auchincloss and Diez Roux, 2008). In this latter tradition, we will focus here on an agent-based model of Human African Trypanosomiasis (HAT), also known as sleeping sickness. Our goal is to show how an ABM approach can improve on conventional modelling methods in assessing the likely success of different policies for managing the disease.

HAT is a neglected tropical disease (NTD) (Simarro et al., 2010) and one of the most common conditions affecting the poorest 500 million people living in sub-Saharan Africa (Hotez and Kamath, 2009). Sleeping sickness is a vector-borne, parasitic disease which is transmitted to humans by the bites of the tsetse fly from the genus *Glossina*. The disease is caused by protozoa of the species *Trypanosoma brucei* - namely the sub-species *T. b. gambiense* and *T. b. rhodesiense* (Fèvre et al., 2008) and, as of 2005, was responsible

for an estimated 100,000 deaths every year (Picozzi et al., 2005).

In recent years, the potential for a spatial cross-over of the two forms of the disease has been heightened due to the continued northward spread of Rhodesian HAT in Uganda (Batchelor et al., 2009). This would be particularly significant as Gambian and Rhodesian HAT require different diagnosis and treatment, and any overlap would compromise previous disease characterisation based on knowledge of the geographical distributions of the diseases.

The resettlement of communities in response to epidemics in the 1900s and 1940s had aided the control of the disease. However, a large volume of uncontrolled movements through tsetse infested bush following a further large outbreak in 1971, combined with a lack of resources and trained personnel, meant that mitigation efforts were hindered in a time of political and economic unrest (e.g. Matovu, 1982; Okiria, 1985). As a result of the poor control measures, the *T. b. rhodesiense* form of the disease spread northwards towards the Tororo district in 1984 (Mbulamberi, 1989), before reaching the Soroti district on the north west shores of Lake Kyoga in 1998 (Fèvre et al., 2004), and the Kaberamaido district in 2004 (Fèvre et al., 2005).

At present, with cases of *T. b. rhodesiense* being diagnosed as far north as the Ugandan district of Lira, there is a distance of only 150 km separating the active foci of Rhodesian sleeping sickness to the north of Lake Kyogo, and the Gambian form of the disease towards the north west of Uganda and south Sudan (Figure 1).

## The vector

Mitigation techniques for sleeping sickness in sub-Saharan Africa often focus on the reduction or the removal of the tsetse fly, which carries the disease. For example, while the burning of tsetse infested bush has fallen out of favour due to the associated environmental damage, other effective techniques have incorporated community led 'vector trapping' to reduce the concentration of the flies (Joja and Okoli, 2001). The associated research concluded that the integration of public participation aided community learning and

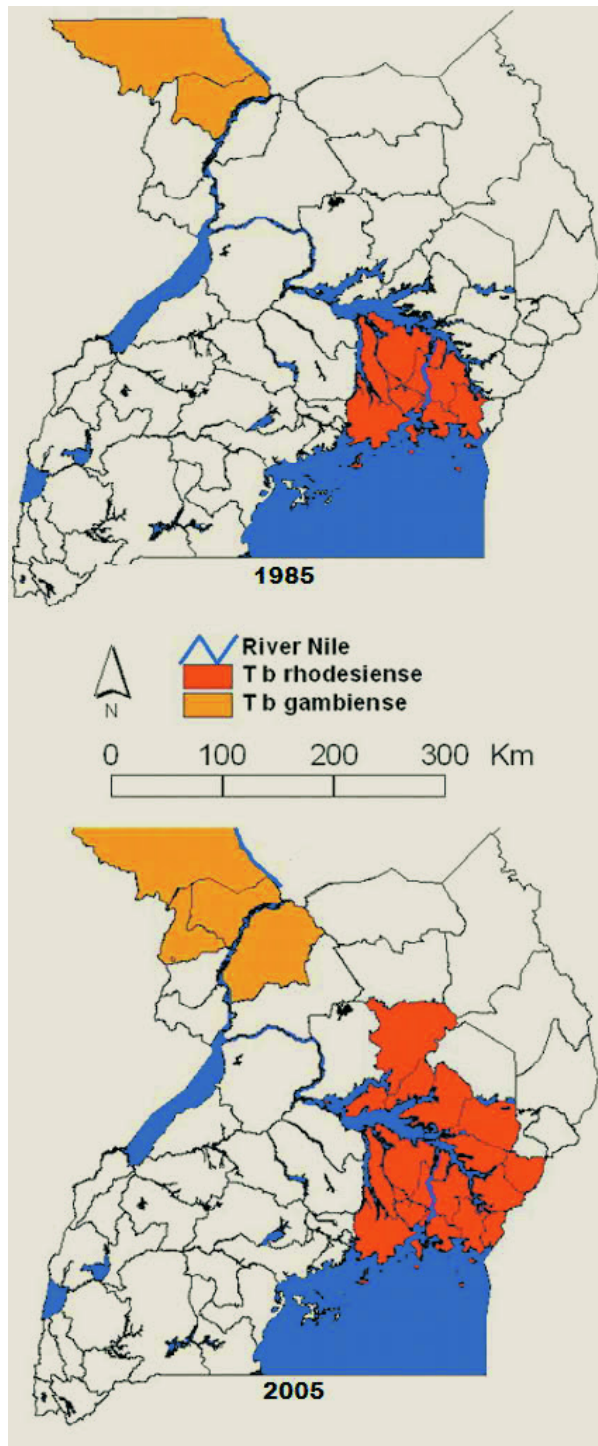

Figure 1: The conversion of Rhodesian (red) and Gambian (orange) sleeping sickness between 1985 and 2005. After Picozzi et al. (2005).

made the volunteers much more open to mass blood screening programmes.

An alternative approach to vector control has been researched in the field of molecular genetics. With the lack of a mammalian vaccine and affordable drugs making disease control difficult, Aksoy (2003) notes that the future of vector control may be the genetic disruption of the parasite transmission cycle in the invertebrate. While this requires a full understanding of the relationship between tsetse and trypanosome, the replacement of susceptible insect phenotypes with anti-pathogenic properties could result in decreased transmission.

Accompany these vastly different mitigation strategies with the application of insecticides such as deltamethrin (e.g. Torr et al., 2007a; Hargrove et al., 2012) to grazing cattle, and a focus on preventative measures which manage tsetse fly population sizes can be identified.

### Agent-based modelling

Lambin et al. (2010) review the merits of using multi-agent simulations (MAS) to model disease transmission, concluding that the technique is a good method of acquiring preliminary knowledge of a disease system, and that the representation of the dynamics of people-vector contacts in space and time are ideal to investigate scenarios that have not previously been observed or explored.

Similarly, the modelling of people-vector contacts is of particular significance given that the majority of current mitigation strategies focus on the control of tsetse fly movement and density. Lambin et al. (2010) also consider the incorporation of geographical information in epidemiological models through the use of MAS, such as the impact of land-use and land cover change. The report suggests that the benefits include an increased knowledge of transmission cycles, allowing the construction of 'pathogenic landscapes' which can subsequently provide an early warning of increased transmission risk. The benefits of incorporating geographical data into epidemiological models can be observed widely in the literature. For example, Raffy and Tran (2005) note that landscape features largely control the connectivity between hosts and vector habitats, inhibiting movement, and ultimately modifying disease risk. One of the least well integrated factors in traditional landscape epidemiology is human behaviour (Lambin et al., 2010). Despite this, different risk perception between men and women, and also by permanent and part-time residents of endemic areas, has been shown to influence the adoption of preventative measures and ultimately vary transmission risk (e.g. Stjernberg and Berglund, 2005).

We therefore saw an opportunity to build an ABM that included the disease vector (tsetse flies) and both host species (humans and cattle) interacting in a common geography so that we could assess the likely costs and benefits of widely differing management strategies for HAT.

Figure 2: The simulated environment; description in text.

### The Model

The simulation incorporates an abstract spatial map and three interacting agents: tsetse flies, humans and cattle, allowing the influence of agent interaction in disease transmission to be explored. The model includes two simple daily tasks for farmer and non-farmer agents: farmers must drive their cattle to the river to drink, before grazing and returning home. Non-farmers must collect water from the river and return it to their settlement. Tsetse flies are assumed to have a natural habitat on, or near the river. Interactions between flies and the ground-based agents occur when the daily tasks take place, and humans and cattle enter the high risk, tsetse infested river area.

We begin with a simple, abstract terrain representing an area of 30 km by 20 km. The simulated land includes a river (blue) at the centre of the canvas, with flood plains either side (green), and the remaining land representing general pasture. Black icons represent small settlements or home bases for human and cattle agents (figure 2).

Within the model, time steps are grouped into the phases ‘night’ (7 pm - 5 am), ‘morning’ (5 am - 8 am), ‘day’ (8 am

- 4 pm) and ‘evening’ (4 pm - 7 pm), simulating a day with 240 time steps. These phases govern agent activity and vary exposure to the disease vector, ensuring that farmers drive their cattle to and from the river each day before grazing and returning to their settlement.

Humans are depicted in the graphical output as orange circles and are divided into farmers and non-farmers. This distinction dictates their movement pattern to and from the river. At setup, all humans are randomly assigned a settlement as a home base, with the initial cattle population randomly assigned a farmer as an owner. During the morning and day phases, all humans are required to have left their home settlements and begun either making a trip to the river to collect water (non-farmers), or driving their cattle to water before grazing (farmers). During the morning phase, there is an initial probability (10%) for each individual leaving their home per time step. When the day phase is reached, any person not to have left home yet is forced to leave.

Movement is governed using a cell desirability function, such that the rows of the map are assigned integer values which are high at the river, and decay to the edges of the

map. People move from home to the river by selecting a desirable cell from a list of their neighbouring locations. When a movement probability is exceeded for each individual, there is a 66% chance they will move to a cell with a higher value (closer to the river), and a 33% chance they will either move closer to the river or make a lateral movement, simulating different routes taken, and the subsequent spreading out of agents.

Non-farmers move directly to their homes when the river has been reached. However, if the people are farmers, a random movement element has been included to simulate the grazing of cattle. Once the cattle have been driven to the river (and whilst still in the day phase) this 'grazing' occurs with a probability per time step of going home (initially 1%). When the evening phase is reached, all remaining farmers drive their cattle to the home settlement. By the 'night' phase, all people and their cattle will have returned to their home settlement and remain there until the next morning phase, when the cycle begins again.

Should people get bitten and become infected with the disease, when they return home, they stay there, and do not resume with the next daily cycle. This simulates the debilitating nature of the disease, preventing people from undertaking their everyday duties.

As previously mentioned, cattle (blue circles) are assigned an owner at initialisation, and are programmed to follow the movement pattern of their keeper. The exception to the rule is when owners become infected and subsequently stay at home for the duration of the simulation. Under these circumstances, the cattle of the infected farmer are redistributed to uninfected people at the same home settlement, during the night phase, so that they can still be driven to the river. The redistributed cattle can be infected or uninfected and this redistribution can continue as more people become ill, until there are no longer any healthy humans in the home settlement. At this point all cattle stay at home, whether infected or not, as there are no healthy human agents to drive the cattle to water.

Tsetse flies are represented as green icons. They stay close to the river and flood plain areas which represent the natural habitat of the species. This behaviour is implemented by assigning each cell on the grid an integer value, with the central 10 rows having a uniformly high value, decaying north and south of the river so that the extreme four rows have values of 0. Tsetse flies have a lower initial movement threshold than humans to simulate faster movement. The random and directed elements of fly movement are not separated to reflect a daily routine as found with humans. Instead, flies are initially set to have a 70% chance of moving using the 'fly suitability rating' of the cells around them (i.e., moving to the neighbouring cell with the highest value). The alternative is a completely random move to any of the agent's 8 neighbouring cells. This movement regime means that, while the majority of flies will stay close to the

river and its banks, some spread is observed as stray flies can move away from their natural habitat and towards the settlements.

In this simulation, flies have a 100% chance of contracting the disease if they bite an infected cow or human, however, if the fly does not bite an infected agent for their first blood meal, the fly is re-spawned at the river to represent the removal and replacement of that agent. This action simulates the finding that flies that don't become infected on their first blood meal are much less likely to contract, and therefore, transmit the disease (e.g. Walshe et al., 2011; Aksoy, 2003). Additionally, once a fly has become infected, there is a 15-30 day delay before it becomes infective, incorporated to reflect a real life incubation period for the disease (Muller et al., 2004).

The transmission of the disease between agents is governed by a bite and infection probability, using values extracted from the literature. At the beginning of each simulation, a single fly is infected with sleeping sickness. Transmission occurs from the point of view of the tsetse fly. For every time step, each fly has a 'potential victim' list, made up of all the human and cow agents in the same cell. If this list is populated, and a randomly generated number is less than the chosen bite probability value, the fly randomly chooses one of the agents in the list as a victim.

Whether or not the bite successfully infects the human or cow agent is governed by another pair of probabilities. As humans and cows are widely considered to be differentially susceptible to *T. b. gambiense* and *T. b. rhodesiense* (e.g. Fèvre et al., 2006), different infection probabilities are incorporated for the different types of agents. The values associated with these three probabilities vary in the literature, due in part to the small sample sizes in data collection, and the complexity involved in the transmission of the disease and vector-host interaction. For example, Torr et al. (2007b) find that cattle bite rates vary with cattle age and herd size, suggesting that mean fly feeding probability can increase from 54% to 71% with an increase in herd size from 1 to 12. We take our infection probabilities from the work of Hide (1999), reporting on the dynamics of transmission of sleeping sickness during the 1988 to 1990 sleeping sickness epidemic. Hide (1999) reports a cattle infection probability of 0.0115, and a human infection probability of 0.006, based on data for the frequency of infected hosts in the population during this period in Uganda.

Consequently, the basic bite probability under investigation will be 0.54, while infection rates of 0.115 and 0.06 will be used to reflect the susceptibility of cows and humans respectively. This uses the same ratios as Hide (1999), however the values have been increased by a factor of 10 to compensate for the unrealistically small population sizes we have used (typically 100 humans, 320 cows and 100 flies). Smaller population sizes have been used as it would be computationally inefficient to attempt to simulate every

fly present in an area this size.

To simplify the simulation, and consider worst case epidemic scenarios, recovery from the disease is absent from the model. While an ideal model would incorporate some form of recovery factor, the degree of variability in diagnosis and treatment rates would be a difficult thing to include in a spatially and culturally abstract simulation.

## Results

Figure 3 shows the progression of transmission of the disease in this abstract environment with 100 humans (including 80 farmers), 320 cattle, and 100 flies over a 6 month period. 6 months was chosen as, in an environment where there is no recovery, this is how long it takes for the disease to affect the vast majority of the population, given the human infection rate of 0.06, and a cow infection rate of 0.115. Bite rate is set at an intermediate value of 0.54, thought to be significant in cattle herds (after Torr et al., 2007b).

Figure 3: Progression of sleeping sickness over 6 simulated months (240 time step days); from single infected fly to complete epidemic. (Bite probability = 0.54, cow infection probability = 0.115, human infection probability = 0.06).

The six month run of the simulation shows that the fly population is the first to reach complete infection, and as suggested above, the fastest rate of cow infection occurs between months 1 (7200 time steps) and 2 (14400 time steps), once fly infection reaches approximately 50%, and sick humans start to be taken out of the equation by staying at home. The simulation shows that although fly infection occurs for 100% of the population, there are approximately 40 cows and under 10 people which are not infected after 6 months. These remaining cows are at a significantly reduced risk of infection as the simulation progresses as it is possible that all people from a certain settlement become ill, meaning that uninfected cows can be left at home with no fit human to take them to water. Even before this occurs, if it is left to

Figure 4: Infection rates of cattle driving farmers and water retrieving children (non-farmers).

one fit person to take an entire settlement's cow population to water, the spatial coverage of this herd is low, the chance of each individual being bitten is low, and a large proportion of the herd may already be infected, reducing the probability of new infections even further. Similarly, the healthy human that drives this large body of cattle is at a significantly reduced risk as the potential victim list for each fly will be more heavily populated. In this sense, even a simple, spatially abstract simulation such as this can help relate to certain theories of transmission, such as that of Torr et al. (2007b), who suggest that although bite probability increases in larger herds, there may be a degree of 'safety in numbers'.

Figure 4 shows the progression of the disease amongst the 80 farmers and 20 non-farmers in the simulation. Prior to running the simulation, one prediction may have been that the infection would propagate at a faster rate among non-farmers than farmers due to the fact that they have no cattle, and therefore when they encounter an infected fly, they are the only potential victim. As the rate of infection for each sub-class appears to be comparable for the first ten victims, this theory appears to be accurate, particularly as there are only 20 non-farmers in the population, compared to 80 farmers.

Figures 5 and 6 show the results from a series of two-month simulations where the ratio of cattle to farmers is systematically increased from 1:1 (80 farmers and cows) up to 1:7 (80 farmers, 560 cows). As before, the infection rates are a scaled representation of those found in the 1988 Ugandan sleeping sickness epidemic (Hide, 1999). These values of 0.115 for cow infection, and 0.06 for human infection, suggest the propagation of a disease which is reflective of the Rhodesian form of sleeping sickness, where cattle are the main reservoir (Batchelor et al., 2009).

Figure 5: Mean human infection (25 repeat runs) while varying the cow population. *T. b. rhodesiense* infection rate (Bite probability = 0.54, cow infection probability = 0.115, human infection probability = 0.06).

Figure 6: Mean cow infection while varying the cow population. *T. b. rhodesiense* infection rate (as figure 5).

With a 1:1 farmer to cow ratio (80 cows), overall infection is comparable between the two agent types by the end of the two month period. This is likely to be a product of the low total population, and a slower spread of the disease as a result. In a scenario where a fly meets a farmer and his cow in a grid square, there is a 50% chance of selecting either, and the bite probability is the same for both (0.54). Therefore, the only factor promoting infection in cows over humans is the infection rate, which is approximately double, but still only represents a 1 in 10 chance of infection. As a result, flies are less likely to meet infected cows or humans at the earlier stages of this two month simulation and, at this time scale, there is little promoting infection in either agent type

Figure 7: Example of a two month run where human and cow populations are both 80.

(see, for example, figure 7). By the end of the simulation almost all flies are infected (graph not shown) yet the relative sparsity of the human and cow populations means that disease propagation is inhibited.

When the cow population is increased to 160, mean human infection also increases, despite the greater proportion of cows to humans. This is likely to be a result of the increased rate at which the disease is transmitted, given that infection amongst the cow population significantly increases from a mean of 50 infections to a mean of 100. Although the mean increase in human infection is slight, it suggests that the idea of 'safety in numbers' does not apply for this population ratio. However, subsequent increases in the cattle population seem to create this effect, with mean human infection reaching a lower limit of 21 when the human to cow ratio is 1:7. At this point, it appears as though the number of new infections that can occur with an increasing cow population has peaked. This is likely to mean that the cow population is no longer the limiting factor in increasing infection, and instead the fly population is. Indeed, at this point the fly to cow ratio is also 1:7, and therefore a two month period may not be long enough for the vector to have a greater impact on the total population.

Figures 8 and 9 illustrate the results of a similar simulation with the infection probabilities reversed (cows = 0.06, humans = 0.115).

This scenario may be expected to produce infection data representative of the Gambian form of sleeping sickness, where humans are the primary reservoir, and cattle are affected to a lesser extent. While there are on average more infections per 100 of the human population than for the cow population, there are a few interesting points to note. Firstly, the range of mean human infection across all initial cow populations is 30-50 people. Compare this to the human infec-

Figure 8: Mean human infection (25 repeat runs) while varying the cow population. Reversed infection rate (Bite probability = 0.54, cow infection probability = 0.06, human infection probability = 0.115).

Figure 9: Mean cow infection (25 repeat runs) while varying the cow population. Reversed infection rate (as figure 8).

tion range in figure 5, which is 21-49, and changing the infection rate of humans between simulations appears to have had little effect, particularly as the shape of the plots is very similar. Although there are significantly fewer cow infections observed in figure 9 than figure 6, the data suggests that human to cattle population ratios and human infection numbers alone cannot be used to distinguish between two distinct infection rate scenarios. While only a simple simulation at this point, one can see how this may have some bearing in the real world, where knowledge of cow infection data would be very useful, but may not be widely available, or easy to collect.

## Conclusion

This report has outlined a growing problem in sub-Saharan Africa: the re-emergence of sleeping sickness at epidemic levels during the 2000s, and the risk that two distinct forms of the disease, *T.b. rhodesiense* and *T.b. gambiense*, may no longer be spatially discrete in the near future. Combine this with inaccurate diagnosis techniques and scarcely available, outdated treatment, and there are urgent reasons to investigate new means of mitigating the disease. Agent-based modelling appears to be a tool which can aid this mitigation, particularly as a significant amount of focus has been given to controlling the spread and density of the disease vector, the tsetse fly. The results from our model do not yet constitute firm predictions as there are several key parameters on which we would like to get improved data, and we have so far used a spatially abstract simulation. However, the project has conveyed the potential for the technique to incorporate a degree of spatial complexity which would be extremely difficult in a purely traditional epidemiological susceptible-infected-susceptible (SIS) model.

While the future spread of sleeping sickness appears uncertain in the affected areas, the exploration of a number of potential scenarios with agent-based modelling appears to be a sensible step in the future study of the epidemiology of the disease. Improvements that we plan to make in the second iteration of this model include a move away from an abstract gridworld in favour of GIS-derived maps of real Ugandan landscapes, allowing the identification of habitats suitable for tsetse flies, suitable watering holes for cattle, and herding routes for farmers. This incorporation of detailed maps (especially at different times of year) will allow exploration of the connectivity between host and vector habitat, which may vary seasonally due to the drying out of lakes, and the associated modification of the tsetse fly risk zone.

In addition, more attention will be given to the possibilities of ABMs for the rich representation of human daily routine and decision-making on key aspects of behaviour that can affect disease transmission. Parameters to explore may include behaviour towards the sick, the distribution of daily tasks amongst the household, the availability/successful undertaking of preventative measures, and the decision to go to a market town despite the risk of infection.

# Cell Division Behaviour in a Heterogeneous Swarm Environment

Adam Erskine, J. Michael Herrmann

a.erskine@sms.ed.ac.uk

## Abstract

We present a system of virtual particles that interact using simple kinetic rules. It is known that heterogeneous mixtures of particles are producing particularly interesting behaviours. Here we present a two-species swarm in which a behaviour emerges that resembles cell division. We show that the dividing behaviour exists across a narrow but finite band of parameters and for a wide range of population sizes. In a two dimensional environment the swarm's characteristics and dynamism manifests differently from those observable in a three dimensional environment. In further experiments we show that repeated divisions can occur if the system is extended by a biased equilibrium process to control the split of populations. We propose this repeated division behaviour provides a simple model for cell division mechanisms, which relates to discussions of the origin of life and is of interest for the formation of morphological structure and to swarm robotics.

## Introduction

We investigate emergent behaviours found arising from the interactions within a heterogeneous swarm. The interactions are in the manner of that originally described by Craig Reynolds (Reynolds, 1987). He introduced a simple algorithm showing that such a swarm could manifest flocking behaviours. Each particle is influenced only by other particles in its local neighbourhood. Each update of the model represents a discrete time step. On each update every particle is drawn toward the centre of mass of its neighbours, aligns its velocity with its neighbours and is pushed away from any particles too close. Reynold's swarms were homogeneous.

Sayama (2009) extended this approach allowing multiple swarms to interact. Each swarm may have different sets of parameters. A set of parameters may be thought of as defining a species. By mixing two or more species of swarms unusual structures and dynamic behaviours have been seen (Sayama, 2010, 2012b,a). Many swarms could be identified that have a distinct biological look to them: cells, amoebas, diatoms abound. It is tempting to see the dynamics of the so-called *swarm chemistry* as a simple model for the real life counterparts of these forms.

We extend the heterogeneous swarm algorithm to include both growth and biased equilibrium mechanisms. Our explorations have found a set of species that show cell division like behaviour. Density and entropy measures allow us to make broad categorizations of behaviours. Single homogeneous swarm show limited behaviours, but more complex emergent behaviours are apparent with just two interacting species. Our investigations explore the robustness of this behaviour under parametric variation. Specifically we studied:

- How cell division is affected by the total size of the swarm and the populations of each subspecies.
- The differences in the behaviour exhibited in 2D and 3D environments.
- How cell division is affected by variation of several of each swarm's defining parameters.

Structure and form abound in and between biological organisms. Much of this comes about via self organization. One benefit of this is that its resultant emergent forms are, in some sense, available for free. Structure emerges from interactions without the need for it to be explicitly coded. An understanding of these rules and their application allow us the possibility of reusing this free structure in robotic systems. Self-organization of structures, self repair or growth without explicit command and control is beneficial. This approach may provide a model that allow us look at the automatic creation of morphological artefacts and dynamic behaviours. The tendency of many swarms to mirror biological forms, albeit superficially, raises the question of whether they can also be a model of biological processes.

Theories on the origin of life often invoke mechanisms to assure that proto-replicators are held in close association: within rock fissures; agglomeration at thermal vents; within the wind blown organic foams formed in the sea. Self-organized structures offer options for such discussions. A similar argument is made (Hutton, 2002) with reference to artificial chemistry. However this model is limited to the organizational dynamics arising from its kinetic interactions.

Single cell division and the dynamics of small multicellular groups contain the ebb and flow of chemical gradients, protein interactions and gene expressions. Whilst much is known, the precise chemo-mechanical details are still there for investigation. We propose that the dynamics of our cell division swarms may offer a simple model that allows some of these investigations. In order to allow this we require that a robust repeating cell division like mechanism be implemented. Thus we also look at modifications made to enable the observed cell division behaviour to repeat.

## Background

D'arcy Thompson detailed many roles that physical processes might play in the morphological development of creatures and their artefacts (Thompson, 1917). He saw that the forms that soap bubbles took as their surface energies pulled and found equilibria bore resemblances to biological forms. He believed that this was not mere coincidence. It has been shown that this idea is indeed true — at least in part. Honeycomb, its hexagonal packing and shape of end caps, are both found in bubble foams but are not derived from a bubble formation mechanism (Ball, 2011). However the packing of the four cones in the ommatidia of a fly's compound eye may be due a mechanism of simple squeezing together like bubbles. Ball also documents work that notes that the spicule structures of sponges appears to form via a mechanism whereby a bubble array is created and then inorganic compounds are allowed to permeate the interstices of the bubble matrix. The creature is leveraging the free structure from what Ball refers to as a fossilized foam. The processes at all scales of life are complex when compared to the simple mechanisms that our model uses. And yet simple processes may shed light on the forms that life can take. Finite subdivision rules have been used to model cell division previously.

Reynolds' flocking algorithm have been subject to numerous variations, adding in: assumed fear, or leadership roles, or desire to stay close to roost sites etc. It has been shown (Feder, 2007) that in starlings it is the number of neighbours (not radius), that is important, and that the influence of neighbours was spatially anisotropic. Nearest neighbour interactions combined with an energy minimization argument has been used to generate line and vee formation flocks (Klotsman and Tal, 2011). These homogeneous swarm algorithms have been further extended by combining multiple 'species'. We should mention here again the studies of Sayama in particular on the relationship between 2D and 3D species (Sayama, 2012b). An evolutionary approach was adopted to discover interesting heterogeneous swarms (Sayama, 2010, 2012a).

Local interactions in biology have been much studied. Quorum sensing, the switching of behaviours due to local sensing, is seen in a large range of organisms from bacteria to honeybees (Miller and Bassler, 2001; Seeley

et al., 2006). Various insects employ local microrules to drive artefact construction (Camazine et al., 2001). It has been shown (Schmickl and Hamann, 2011; Kengyel et al., 2009; Bodi et al., 2009) that bees, through local interactions, locate areas of a target temperature. Such biological inspirations have informed swarm robotic work. Review documents (Bayindir and Sahin, 2007; Mohan and Ponnambalam, 2009) highlight the extensive range of behaviours that may be implemented from swarm robotic interactions, including: pattern formation; aggregation; chain formation; self-assembly; coordinated movement; hole avoidance; foraging; self-deployment; grasping; pushing; caging.

## Method

The basic heterogeneous swarm algorithm (Sayama, 2012b) gives each particle a set of parameters. Each particle's update of position and velocity is influenced only by its local particles within a specific neighbourhood radius. Each particle has a preferred normal speed, the maximum speed being bounded. Parameters  $c_1$ ,  $c_2$  and  $c_3$  scale the influence of the neighbouring particles. The  $c_1$  parameter is a measure of cohesion, the strength of pull toward the mean neighbour position. The  $c_2$  parameter is a measure of alignment, the strength of pull toward mean neighbour velocity. The  $c_3$  parameter is a measure of avoidance, the strength of push from close neighbours. On each update of the swarm each particle uses neighbouring particles to update its position and velocity.

$\mathcal{N}$  is the set of particles centred on particle  $i$  and being within particle  $i$ 's neighbourhood radius. The average position of these is

$$\langle \mathbf{x} \rangle = \frac{1}{|\mathcal{N}|} \sum_{j \in \mathcal{N}} \mathbf{x}_j.$$

The average velocity of the particles within the neighbourhood radius of particle  $i$  is

$$\langle \mathbf{v} \rangle = \frac{1}{|\mathcal{N}|} \sum_{j \in \mathcal{N}} \mathbf{v}_j.$$

The acceleration of particle  $i$  is given by

$$\begin{aligned} \mathbf{a}_i = & -c_1 (\mathbf{x}_i - \langle \mathbf{x} \rangle) - c_2 (\mathbf{v}_i - \langle \mathbf{v} \rangle) \\ & + c_3 \left( \sum_{j \in \mathcal{N}} (\mathbf{x}_i - \mathbf{x}_j) / |\mathbf{x}_i - \mathbf{x}_j|^2 \right). \end{aligned}$$

The dynamics are further modified by the  $c_4$  parameter which is a probability of ignoring the neighbours' effects. The particle's velocity is updated using the acceleration  $\mathbf{a}_i$ .

$$\mathbf{v}'_i \leftarrow \mathbf{v}_i + \mathbf{a}_i.$$

The magnitude of a particle's velocity has an upper bound. This is one of the swarm's parameters. Similarly each swarm has a parameter that is the preferred magnitude of the particles velocity. If a particle is not travelling at this preferred velocity,  $\mathbf{v}_n$ , then parameter  $c_5$  is then used to nudge the velocity back to its toward its preferred velocity using

$$\mathbf{v}_i \leftarrow c_5 (\mathbf{v}_n / |\mathbf{v}_i'| \cdot \mathbf{v}_i') + (1 - c_5) \mathbf{v}_i'.$$

Finally each particle's position is updated using

$$\mathbf{x}_i \leftarrow \mathbf{x}_i + \mathbf{v}_i.$$

## Quantification

The eight parameters ( $c_1$  through  $c_5$ , neighbourhood radius, speed and maximum speed) define a large parameter space. To search this space we require automated means to detect behaviours of interest.

In our swarms we can calculate the average density of particles. This density measure differentiates single blobs from both dispersed swarms and multiple blobs: single blobs show a higher density. We note that this may not always be true: a large hollow single blob may be less dense than multiple blobs that are close together. A second measure, a spatial entropy, allowed differentiation between multiple blobs and dispersed swarms. It has been suggested (Bonabeau et al., 1999) that a spatial entropy can be defined as

$$H = - \sum_k P(k) \log P(k),$$

where  $P(k)$  is the fraction of particles found in patch  $k$ .  $H$  decreases as clusters form. We used patches that are always cubes of side 0.1 times the maximum extent of the swarm i.e. the minimal cube containing the swarm is split into 1000 patches. Two similar treatments are made in (Batty, 1974) and (Wolfram, 1984).

We also use the Kullback-Leibler divergence from an evenly distributed population as a measure. This is defined by

$$D_{KL} = \sum_k P(k) \log \left( \frac{P(k)}{Q(k)} \right),$$

where  $P$  is the distribution of the particle positions and  $Q$  is the distribution of an evenly dispersed swarm. Note that since  $Q$  is evenly distributed, we have simply  $D_{KL} = \log \left( \frac{1}{Q(x)} \right) - H$ . For the cell division like behaviour  $D_{KL}$  thus increases when the swarm has divided into separate clumps.

Fig. 1: Typical evolution of cell division in our swarm. Top left shows red particles as a toroid about the yellows. Top right shows the yellow swarm divided in two with a separate red swarm. Bottom left has the reds rejoining the larger yellow blob. Finally bottom right, the process repeating and is shown at a larger scale.

## Results

### Single species characterization

A homogeneous swarm appears to exhibit behaviours drawn from a fairly limited palette of possible behaviours. We note four behaviours: full dispersal, blob or sphere, multiple blobs, and one we call a point swarm (all particles collapse toward a single point). In full dispersal the particles separate and move apart, there is little or no tendency to aggregate. In a blob the particles form a sphere (or approximate sphere) or shell of a sphere. Multiple blobs are simply a multiple version of the last form. Point swarms are seen for swarm parameters where the avoidance value is at or near zero. This results in all particles collapsing to a single point. This state tends to not show as a sphere or a point. Instead the particles, which all exist in a tiny spatial volume, show as an irregular clump of particles that jump about. Particles have discretised speeds so at each update a particle tends towards the average position of the clump, but the step size is larger than the size of the clump, thus the particles are unable to actually occupy a single point.

We find that the four single species states can be classified by the density and spatial entropy (or Kullback-Leibler divergence). By sweeping through the parameter space of the cohesion and avoidance parameters it was possible to find regions of each of the four swarm types. The spatial entropy and densities were measured for each. A visual check of the final state of the swarm was also made. The

Fig. 2: Density and entropy measurements for a homogeneous swarm as a function of its cohesion ( $c_1$ ) and avoidance ( $c_3$ ) parameters. The logarithm of each measure is plotted in order to squash the vertical extent of the surface plots as the range of values extends over several decades.

measures were plotted against the parameters to generate the surface plots shown in Fig. 2.

### Cell division behaviour species

We present two species of swarms that individually formed single blobs (multiple blobs if their populations were large enough), but in combination result in a cell division like behaviour. Typical stages of this are shown in Fig. 1. The values for the parameters used in these swarms are shown in Tab. 1.

spc	rad	spd	msh	$c_1$	$c_2$	$c_3$	$c_4$	$c_5$
1	20.5	1.94	20.7	1	1	18.6	0.05	1
2	300	15.58	37.08	1	0.05	9.11	0.47	0.61

Tab. 1: Parameter values for the cell division like behaviour swarms. Headings are: spc = swarm species, rad = neighbourhood radius, spd = normal speed, msh = maximum speed,  $c_1$  = cohesion,  $c_2$  = alignment,  $c_3$  = avoidance,  $c_4$  = whim,  $c_5$  = speed control.

When displaying the particles the parameters  $c_1$  through  $c_3$  are used to define the displayed colour of the particles. Here, species 1 displays as a yellow colour and species 2 as a red colour. Clearly if we alter these parameter values the colours will alter. For descriptive convenience we choose to describe the two swarms as the yellow and the red swarms respectively. Typically the swarm population constructed of around ten yellow particles for every red particle. When this heterogeneous swarm is run the initially mixed species separate. A toroid of red particles forms about the yellows until a split occurs. The separate yellow blobs move apart, with the red particles forming a blob in between. At some

point the reds are drawn into one of the yellow blobs and the process repeats. The repetition only occurs within a single blob of the yellows.

### Comparison with 2D Swarm Chemistry

We explored the differences in 2D and 3D behaviour of our swarms. With no change to the swarm parameters cell division behaviour still occurred. Differences in the 2D version included: the red particles travel to the inside of a yellow circle of particles causing an inside out division to occur; the separated blobs do not travel apart; and the red particles do not get drawn back into one of the yellow blobs.

An outside in division was achieved via modification of both swarms' parameters, Fig. 3. As parameters have been changed, the particles no longer appear as red and yellow but as magenta and cyan respectively. Now the red particles form a ring around the yellow circle and squeeze it until division occurs. Again the separate parts do not travel apart.

It is possible that reintegration of the red particles with one of the yellow blobs would occur if the swarm was left to run. It is also possible that with further parameter modification a recipe may be found that results in the split parts separating.

### Robustness under population dynamics

**Yellow versus red populations.** We varied the two species' populations to determine the limits on the cell division like behaviour. Each run lasted for 2000 time ticks. The density and entropy measures were captured at the end of each run. For confirmation the final state of the swarm was captured as an image. Yellow populations were varied over a range from 100 to 550 in steps of 50, and red population over the range 10 to 90 in steps of 10. Fig. 4

Fig. 4: Density and entropy measurements for a heterogeneous swarm as a function of its yellow and red populations ( $p_1$  and  $p_2$ ). The logarithm of each measure is plotted in order to squash the vertical extent of the surface plots as the range of values extends over several decades.

Fig. 3: 2D cell division. Upper row shows an ‘inside out’ division. Lower row shows an ‘outside in’ division.

shows the density and entropy measures as a surface plot for all combinations of these populations. Cell division is marked by low density (blue on left hand plot) and high entropy (red on right hand plot). We see that the cell division behaviour extends over a wide range of populations. Very low red or high yellow populations tend to never show cell division. The line between division and no division is noisy. We assume this is due to variability in starting position of particles and/or the arbitrary duration of each run. We explore both of these possibilities.

We fixed the red population at 50, and executed 5 runs for yellow populations varying from 300 to 600 in steps of 25. When the yellow population is below 375 division always occurred. For populations above 450 it never occurred. In the range between division may or may not occur. The difference between each run was the randomized initial positions of the particles in the swarms. The KL divergence and the density (averaged over the 5 runs) are summarized

in Fig. 5. The density increases and the KL measure drops above a population of 350 coinciding with the onset of swarms that fail to divide. When division never occurs the values level off.

Fig. 5: Density and Kullback-Leibler divergence measures as function of yellow population after 2000 time ticks. For a fixed population of red particles (50), we vary the population of the yellow swarm (from 300 to 600).

**Effect of lengthening run time.** We repeated the previous investigation but allowing the model to run now for 10000 steps. There is still no distinct population boundary between split/no split behaviour. Yellow populations less than 425 always result in division. Those greater than 475 never divide. Populations between these limits may divide. Fig. 6 confirms this observation in that the step up in density occurs at higher yellow populations. Executing the swarm for still

Fig. 6: Density and Kullback-Leibler divergence measures as function of yellow population after 10000 time ticks. For a fixed population of red particles (50), we vary the population of the yellow swarm (from 300 to 600).

longer durations suggested that with relatively small red swarms the whole swarm may be unable to divide. However when the red population was increased (to 180) the swarm which appeared to be stable would occasionally eject a small blob of yellow particles. This suggests that such a swarm may slowly lose yellow particles until the remaining yellow blob is small enough to show the normal division behaviour.

### Robustness under parameter variation

A full search of the parameter space is currently too onerous. Therefore we choose a simpler approach. We look to vary single parameters whilst keeping all other parameters unchanged. We vary the parameter being studied until the cell division behaviour disappears.

**Variation of neighbourhood radius.** Using a yellow:red population mix of 300:50 we varied, independently, the neighbourhood radii of each swarm. For cell division behaviour the red species was required to have a neighbourhood radius greater than 125 and for the yellow ‘species’ it needed to be within the range of about 13 to 25. Samples are shown in Fig. 7. Each swarm was run for 2000 time ticks. Yellow radii above 28 result either in a single cloud or have the red particles held within the yellows.

**Variation of avoidance and cohesion parameters.** We separately swept through combinations of avoidance and cohesion parameters. First we varied red avoidance between 5 and 40, yellow between 10 and 60. Then we varied the red and yellow cohesion values from 0.2 to 1.0. A number of different behaviours were noted. Several behaviours would not be distinguishable via the use of measurements alone, so each run was watched and categorized. A single run of each permutation was made. All runs lasted 2000 time ticks. Tab. 2 shows the results for avoidance variation and Tab. 3

(a) Red radius = 100, yellow radii of 10, 20, 30.

(b) Red radius = 125, yellow radii of 10, 20, 30.

(c) Red radius = 300, yellow radii of 10, 20, 30.

Fig. 7: Final states of each run. Examples of neighbourhood radius variation.

shows the results for cohesion variation.

Cell division behaviours exist over narrow ranges of both these parameters. Cell division behaviour of the sort we have been looking at is thus very sensitive to the values of both avoidance or cohesion parameters. As with the other parameter studies whether this is true for other population and parameter mixes is unknown. It appears that for small yellow avoidance values ( $c_3 \leq 40$ ) the red avoidance value needs to be around half that of the yellow value for any division to occur. Given the parameter set of the swarms, it appears that larger yellow cohesion values are needed to stop the yellow swarm from disintegrating. Perhaps above this level (around 0.6) the yellow swarm requires a greater ‘pull’ from the reds to begin to divide. As with the other parameter studies whether this is true for other population and parameter mixes is unknown.

### Repeated division

The cell division behaviour in the previous sections splits a clump of yellow particles in two. Only one of those clumps will subsequently divide again. This occurs as the red particles tend to only associate with the larger clump of yellow particles. In order for this division behaviour to be seen as a possible model for real world division we needed a mechanism that would allow any yellow clump to potentially divide. In (Sayama, 2012a) each particle is modelled as expressing one parameter set drawn from a group of parameter sets. This formulation allowed a

Avoidance values	Yellow=10	Yellow=20	Yellow=30	Yellow=40	Yellow=50	Yellow=60
Red=5	3D	2D	2D	2D	2D	Y
Red=10	0	3D	2D	2D	2D	2D
Red=15	0	0	0	3D	3D	2D
Red=20	0	0	0	0	3D	2D
Red=30	0	0	0	0	3D	Y
Red=40	0	0	0	0	3D	Y

Tab. 2: Division types as function of avoidance parameter,  $c_3$ , for a selection of the parameter variations tried. Categories are: ‘0’ — No division seen, reds may form toroid round yellows. ‘3D’ — Division seen, behaviour was characteristic of the standard 3D cell division. ‘2D’ — Considered the same as 2D case. Inside out split but clumps are largely static after split. Reds may be drawn in. ‘Y’ — Yellows disintegrate into small clumps, reds form their own clump.

Cohesion values	Yellow=0.2	Yellow=0.4	Yellow=0.6	Yellow=0.8	Yellow=1.0
Red=0.2	Y	Y	Y	0	0
Red=0.4	Y	Y	3D	0	0
Red=0.6	Y	Y	0	0	0
Red=0.8	Y	Y	3D	0	0
Red=1.0	Y	2D	2D	3D	3D

Tab. 3: Division types as function of cohesion parameter,  $c_1$ . Categories are as per Tab. 2.

natural extension to evolutionary techniques to be applied. We choose a similar approach. Each particle expresses itself either as a red or a yellow particle. There is a small probability that any particle may change the behaviour it expresses. This is modelled as a biased equilibrium processes. Each yellow, on being chosen to pick a behaviour, will select changing to red with a 0.1 probability. Each red will select changing to yellow with a 0.9 probability. This ensures a rough 90:10 percent mix in the population, but allows any clump of yellow particles to develop a red population. This mechanism only works as a divided cell tends to move apart. If the parts remain close, either by artificial confinement or as would be the case in the 2D version, then any new reds in one clump tend to be immediately sucked into the clump with the larger red population.

This mechanism alone provides for each clump to continue to divide over time. However, as clumps do not

Fig. 8: Repeated division. Top left shows first division. Top right shows the second division. Bottom Left shows multiple blobs with red particles from the bias equilibrium process. Bottom right shows multiple divisions occurring.

tend to recombine the ultimate future for this approach is a dispersed swarm. We added a growth mechanism to allow clumps to increase in size. New particles would be created close to randomly chosen existing particles. This can be viewed as new particles being recruited from the environment. Fig. 8 shows some examples from a swarm that implements both the biased equilibrium and growth mechanisms. The swarm still tends to appear somewhat dispersed, however, there are still many clumps that continue to divide.

## Discussion

We presented a heterogeneous swarm that exhibits cell division like behaviour. Prior to dividing, the red particles form a toroid — but only because the yellows support it. There are configurations where this appears a long lived phenomenon. Division occurs for a wide range of swarm sizes, but there appears to be a size above which the yellow swarm tends to stability. We found some evidence that such a swarm may gradually lose yellow particles suggesting that cell division may reappear if the swarm runs for long enough. Balancing the growth and biased equilibrium can be hard and the population will tend to fragment. It would be appealing to improve the linkage between these mechanisms so that division would become more regularly periodic.

We observed differences in the emergent behaviour depending whether the swarm ran in a 2D or 3D environment. If the parameter values used in a 3D environment were used, unchanged, in a 2D environment

then we observed an ‘inside out’ division. This resulted in a relatively static set of divided clumps. By modifying the parameter values used we were able to recapture the ‘outside in’ division seen in 3D. This still failed to show the full dynamics seen in 3D. However, the fact that there are parameter mixes that show behaviour in 3D that matches that seen in 2D suggest the opposite may also be true.

The cell division behaviour was sensitive to the swarms’ parameter recipes. Yellow neighbourhood radius needs to be in a narrow band. The red neighbourhood radius appears to have a lower limit, while much larger values seem to result in division behaviour. Cell division behaviour is seen only across a narrow band of both avoidance and cohesion parameters. On one side of the band no division is observed. On the other side either an ‘inside out’ division similar to that seen in 2D, or a spontaneous yellow disintegration that requires no interaction with the red particles, is observed.

The inclusion of a biased population equilibrium and growth mechanisms enabled the swarm to show ongoing cell division like behaviours.

### Abstract

The emergence of antibiotic resistant bacteria is a major threat to public health and there is a constant need for education to limit dangerous practices. Here, we propose to use alife software to develop training media for the public and the physicians. On the basis of the Aevol model we have been developing for more than six years, we built a game in which players fight bacterial infections using antibiotics. In this game the bacteria can evolve resistance traits, making the infection more and more difficult to cure. The game has been tested with automatic treatment procedures, showing that it behaves correctly. It has been demonstrated during the French "Nuit des Chercheurs" in October 2012.

### Introduction

The rapid spread of antibiotic resistant bacteria is a growing threat to public health. Attempts to fight this threat include searching for new antibiotic molecules, understanding the evolutionary dynamics of resistance traits and organizing health care services to avoid dissemination of resistant bacteria. However, all specialists and authorities agree that the most important challenge to fight resistance is education. As Stuart B. Levy already argued in 2002: "Much work is needed on education of the consumer and the prescriber" Levy (2002). In many countries, large awareness campaigns were conducted, but even after ten years, (Bush, 2011) still claimed that "substantial increases in public education about bacteria and antibiotic importance are vitally important". Despite fundings from international and national agencies and the enrollment of non-profit organizations, the basic laws of antibiotic resistance are still very poorly known by the public, leading to maladapted usages that favor the spread of resistant strains.

One of the difficulties when teaching antibiotic resistance is that many factors are intertwined, leading to messages that might sound contradictory (e.g., limit antibiotic usage *but* systematically finish your treatment even though you feel you are cured!). To understand the resistance problem, one needs to grasp the entire evolutionary dynamics of antibiotic resistance, from the selection of resistant mutants to their

spread in a bacterial population (MacCallum, 2007). In particular, one must understand the paths that can lead to higher resistance levels (Almahmoud et al., 2009; Weinreich et al., 2006). These dynamics are far from trivial and are influenced by many parameters: the mutation rate, the population size, population bottlenecks or the fitness cost of resistance. As a matter of fact, the very principles of evolution are poorly known by the public and even by physicians.

To facilitate the understanding of the microbial world and dynamics, computer games have been developed like e-Bug (Lecky, 2011; Farrell, 2011), Bait (Kerr, 2005) or the virtual infection control simulation (Pulman and Shufflebottom, 2009). These programs emphasize the population dynamics of the resistant and susceptible bacterial strains with or without different antibiotics but they do not include evolution *per se* and cannot account for resistance appearance and increase. Although attempts to include evolutionary algorithms in games are numerous, they mainly focus on the evolution of avatar behavior (Grand and Cliff, 1997; Stanley et al., 2005) and often take many freedoms with the real evolutionary phenomena (Bohannon, 2008). We argue that artificial life evolutionary models have a huge potential to develop educational games and that too little work has been done in this direction, except for few occasional attempts (Adami Lab. and Beacon center, 2013; Miglino et al., 2012).

Here, we present the "Aevol Serious Game", based on the Aevol model of bacterial evolution. The game idea is quite simple: the player fights a series of bacterial infections with five different antibiotics: *prokarycin*, *microbicin*, *bactericin*, *bacillicin* and *aevolicin* (all antibiotic names but the last one have been chosen to enable the teacher to explain what is a "microbe"). The player controls which antibiotics are delivered and at what doses. The availability of five antibiotics allows to modulate the treatment strategies to fight the infections. Of course, at the beginning of the game, one can cure an infection very simply by setting one or more antibiotics to the maximum for a few generations. However, the artificial bacterial colony may evolve antibiotic resistance traits that make it more difficult to cure subsequent infections. Moreover, the acquired resistance traits directly depend on the

way antibiotics have been used previously and these effects cannot be cancelled. Thus, as the game goes on, it becomes increasingly difficult to kill the bacteria and to fight infectious diseases.

We first present how the evolving bacterial population is modeled. We then illustrate the model behavior with a simulated player who delivers antibiotics in various automatic ways. Finally, we report how non-scientific players used the game during “La Nuit des Chercheurs” in October 2012.

## Modeling the evolving bacterial population

The Aevol model (<http://www.aevol.fr>) was developed to study the evolution of genome structure and the influence of indirect selection pressures for robustness or evolvability, see Knibbe et al. (2007, 2008). We present here an adapted version of the model, aimed at teaching non-scientific public about antibiotic resistance in the context of evolution. The model is organized as a generational evolutionary algorithm, each generation consisting in three main steps: genome decoding, selection and reproduction with both local mutations and chromosomal rearrangements.

## From genotype to phenotype

The genotype-phenotype mapping in Aevol was inspired by the microbial transcription and translation processes. Each artificial organism owns a genome organized as a circular double-stranded binary string containing a variable number of genes separated by non-coding sequences (figure 1). A set of signaling sequences is used to identify the regions that will be transcribed into mRNAs and within those the ones that will be translated into proteins.

Transcription initiation and termination sites are directly inspired by bacterial genetics. In Aevol, we defined a promoter as a sequence close enough to a predefined consensus and a terminator as a short sequence able to form a stem-loop structure. When a promoter is found, the transcription proceeds until a terminator is reached, thus producing an mRNA whose expression level directly depends on the promoter quality.

Translation occurs when a ribosome-binding site is present on an mRNA, followed by a START codon. Then, the following sequence is read three bases (one codon) at a time, until an in-frame STOP codon is found. Each codon is translated into an abstract “amino-acid” using an artificial genetic code (figure 1).

An artificial chemistry (Dittrich et al., 2001) was defined to model the protein activity and the resulting phenotype. We defined an abstract, one-dimensional space  $\Omega = [0, 1]$  of possible cellular processes (therefore, in this model, a “cellular process” is a real number). Each protein can either realize or inhibit a particular set of these biological processes with a certain efficacy. For simplicity, we use piecewise-linear functions with a symmetric, triangular shape. Hence

the activity of a protein can be fully characterized by the position  $m$  of the triangle on the axis, its half-width  $w$  and its height  $h$ .

A protein’s primary sequence is viewed as three interlaced binary sequences that code for  $m$ ,  $w$  and  $h$  values (see figure 1). Small mutations in the coding sequence will change these parameters, resulting in a modification of the protein activity. Once all proteins encoded by a given genotype have been identified and characterized, their activities are combined into a global fuzzy set representing the individual’s phenotype  $P$ . The possibility distribution of  $P$ , called  $f_P$ , indicates to what extent the individual can realize each abstract cellular process.

For the game, the interval  $\Omega = [0, 1]$  of cellular processes is divided into 7 subintervals (figures 1 and 3). The first ( $\Omega_0$ ) and last ones ( $\Omega_6$ ) represent sets of abstract metabolic processes and they are used to determine the performance of the individual in the competition for reproduction (see below). The five intermediate zones ( $\Omega_1$  to  $\Omega_5$ ) correspond to resistance traits respectively against the five antibiotics. The proximity of these traits along the functional axis facilitates multi-drug resistance (a common feature in bacteria) through pleiotropy since a single triangle can span 2 contiguous zones.

## Environment, fitness measure, death and competition

In Aevol, the environment is represented by a phenotypic target: a fuzzy set  $E$  defined on  $\Omega$  whose possibility distribution  $f_E$  indicates the optimal degree of possibility for each “metabolic process”. To evaluate an individual, we compare its phenotype  $P$  to the optimal one  $E$ . The “gap with target”  $g$  is computed as the geometric area between these two sets on the “metabolic” subintervals (figure 1):  $g = \int_{\Omega_0} |f_E(x) - f_P(x)| dx + \int_{\Omega_6} |f_E(x) - f_P(x)| dx$ . The lower the gap, the fitter the individual. This penalizes both the under- and over-realization of each metabolic process.

Cells can die with a probability  $P_{death} = 20 \times g$  if  $g < 0.05$ , or  $P_{death} = 1$  if  $g \geq 0.05$ , implying that some mutations are lethal. This mortality process, not present in the original Aevol model, was introduced in the game because antibiotics may cause severe population bottlenecks, which are known to make selection less efficient and allow mildly deleterious mutations to accumulate in the population (an effect used by microbiologists in “mutation accumulation” experiments (Korona, 2004)). Making highly deleterious mutations in the game actually lethal prevents them from propagating during the population bottlenecks. In the runs below, typically around 20% of the individuals die at each generation through this mortality process.

Cells can also die because of an antibiotic treatment. Although antibiotics can act on different bacterial subsystems (Normark and Normark, 2002), in this first version of the game, we simply simulated an effect on cell mortality de-

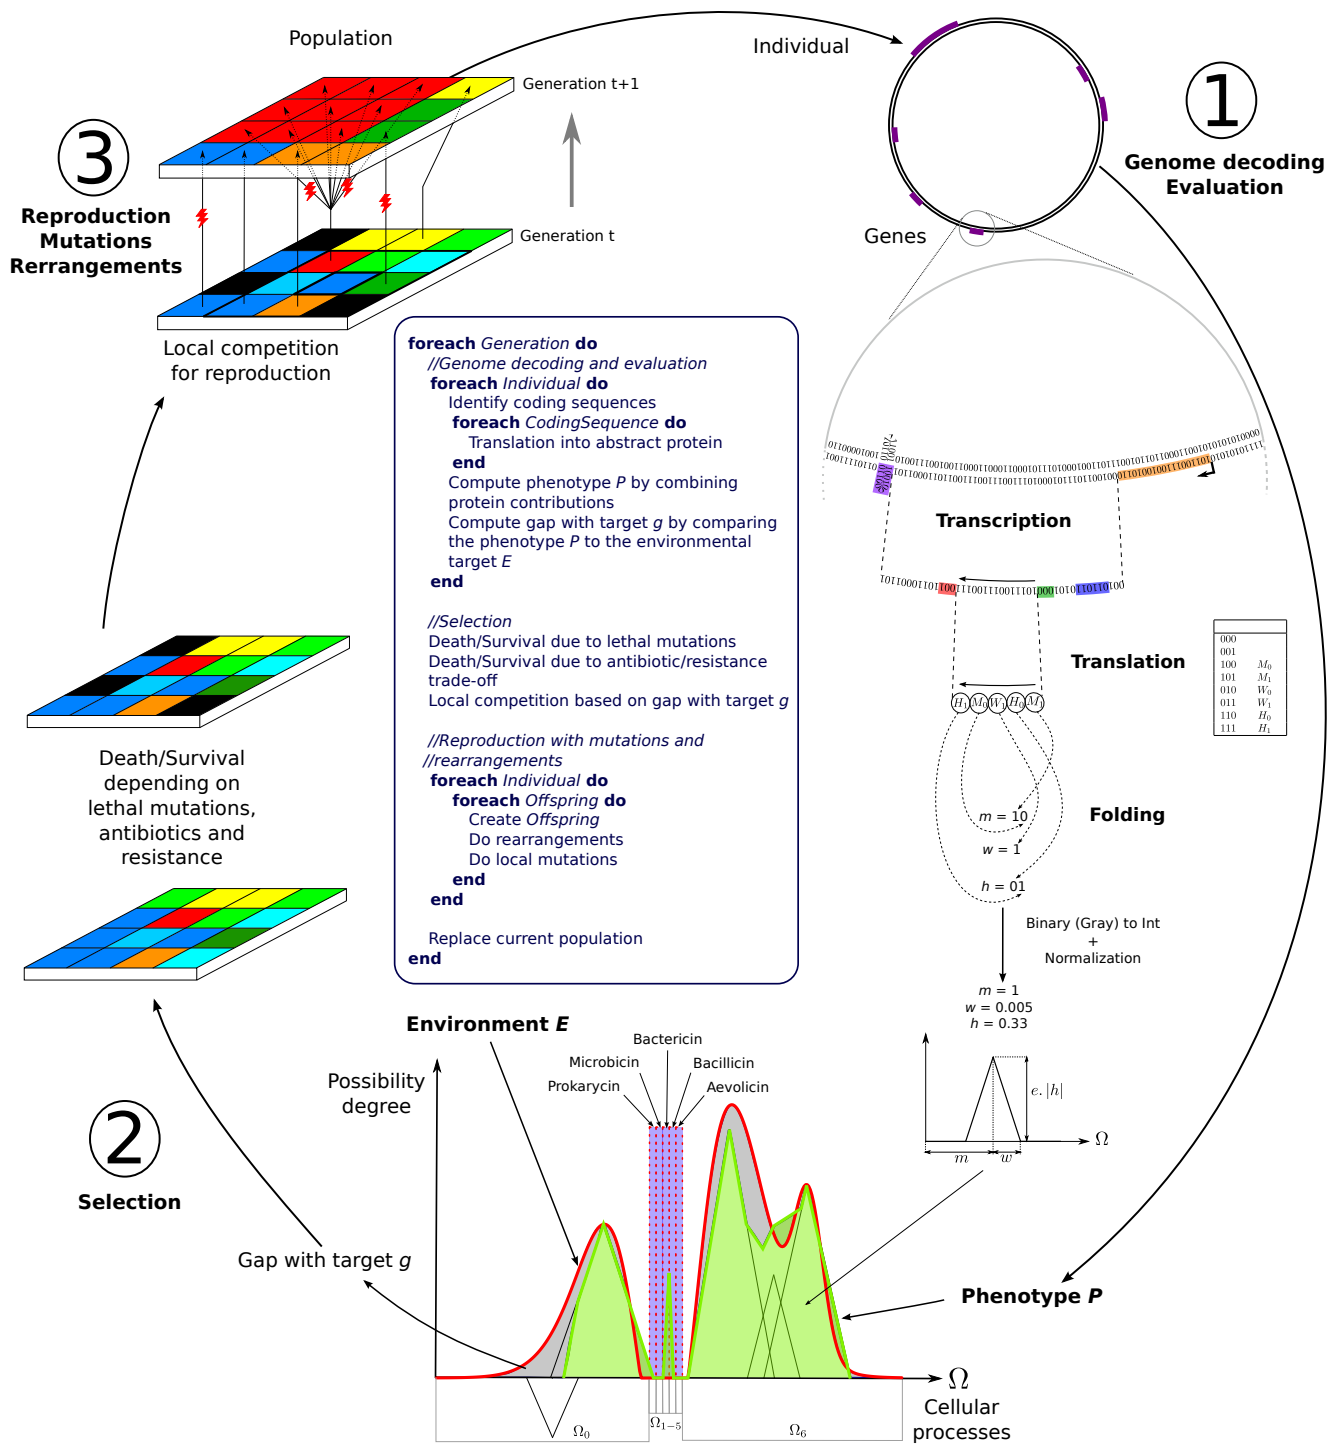

Figure 1: Graphical representation of the AevoI algorithm with antibiotics. The algorithm iterates three main steps: (1) genome decoding and evaluation, (2) selection of the best individuals and (3) reproduction with mutations and rearrangements. See the main text for details. The lightnings correspond to mutations and rearrangements undergone during reproduction. Cells on the grid are colored according to gap with target, red cells being those with lowest  $g$  and blue cells being the higher ones. The dead cells are the black cells. The violet zone on the cellular process axis ( $\Omega_1$  to  $\Omega_5$ ) correspond to resistance traits (one zone per antibiotic).

pending on antibiotic dosage. When a cell receives an antibiotic  $i$  with a dosage  $\alpha_i$  ( $0 \leq \alpha_i \leq 1$ ), it has a probability  $P_{antibio.i} = 0.9 \times \alpha_i$  to die<sup>1</sup> except if it is protected by a resistance trait. The resistance traits to the antibiotics are deduced from the phenotypic function within the  $\Omega_1$  to  $\Omega_5$  zones (one zone per antibiotic, figure 1). The probability to survive a treatment with a given antibiotic  $i$  is:  $P_{resist.i} = 1 - 100 \int_{\Omega_i} |0.5 - f_P(x)| dx$ . There is no direct cost to resistance. However, since resistance is generally acquired through mutation of existing genes, indirect costs are very likely to occur. If more than one antibiotics are delivered simultaneously, the same process is applied for all the antibiotics.

Cells are placed on a  $40 \times 40$  grid (Misevic et al., 2012). Each grid spot contains either a living or dead cell (figures 1 and 3). Local competition for reproduction takes place between living cells only. The population is entirely renewed at each generation. Specifically, each grid spot at generation  $t + 1$  is filled with an offspring from one of the neighboring living cells at generation  $t$  (note that this offspring can die immediately, e.g. if it undergoes a lethal mutation). The cell that will produce the offspring is drawn according to a reproduction probability  $P_{reprod}$  that decreases with  $g$ . If none of the 9 neighboring spots contained a living cell at generation  $t$ , the spot is left unchanged.

### Reproduction, local mutations, rearrangements

During their replication, genomes can undergo both local mutations (single nucleotide substitutions, and insertions or deletions of 1 to 6 bp) and chromosomal rearrangements (duplications, deletions, translocations and inversions). Here, all local mutation occurred with probability  $\mu_{mut} = 1 \times 10^{-5}$  per bp per generation and all rearrangements with probability  $\mu_{rear} = 1 \times 10^{-6}$  per bp per generation. Not all mutational events have a phenotypic effect. For example, a mutation in a region that is not transcribed will most probably be neutral (except if it occurs in a promoter). Because Aevol allows for gene duplication and divergence, it can evolve new functions (e.g. antibiotic resistance traits) and not only modify existing ones.

### Evolution of wild-type strains

Before the game itself, the software was used to evolve a “wild-type strain” in the same environment as used for the game without antibiotics. Here, we used a strain that evolved for 100,000 generations. Its genome is 80,920 base-pair long and has 106 coding sequences present on 101 coding mRNAs. It is well adapted to its environment ( $g \approx 0.006$ ), ensuring that slightly deleterious mutations can accumulate without being immediately lethal.

<sup>1</sup>The 0.9 factor prevents the population from being killed all at once: at maximum dosage the infection is cured in 8 to 10 generations if no resistance evolves. Note that, for pedagogical reasons,  $\alpha$  is always displayed as percentages of the maximal dose.

### Simulating infection

During the first steps of the game, driving the population to extinction is easy since the wild-type is highly susceptible to antibiotics. In such case, the game can go on with a reinfection (triggered by the player). Then the cell with the lowest  $g$  switches from dead to alive. The resistance traits are thus more difficult to maintain since they are not considered in the choice of the “resuscitated” cell, thereby mimicking an infection from an antibiotic-free environment. The resistance traits are actually eliminated unless they were carried by the individual with the best  $g$ , a situation that usually occurs when the resistance traits were useful for a very long period (long enough to enable fixation of these traits despite their mutational load). After reinfection, the germ progressively colonizes all the grid, showing circular patterns where central cells accumulate fewer mutations than peripheral ones (figure 2). This pattern reproduces a known property of population expansion: mutations accumulate on the expanding fronts (Excoffier and Ray, 2008).

Figure 2: Population expansion during an infection process (here at  $t = 1, 5, 10, 15$  and  $20$  generations after the reinfection). Cells are colored according to fitness, red cells being those with highest fitness (lowest  $g$ ) and blue cells being the worst ones. The circular pattern is clearest at  $t = 15$  and  $t = 20$  where many blue cells are observed in the periphery of the infection, while the central zone contains mainly orange and red ones.

### Graphical outputs

The Aevol game is not designed to be used by the player alone but with a supervisor who can explain in real time the effects of the treatment and advise the player. The graphical outputs (figure 3) were designed accordingly. On the left panel, the player can see the whole population on the grid, each living cell being represented by a square, colored according to the gap to target  $g$  of the individual. This panel also displays the current antibiotic dosages that can be changed through the keyboard. It allows the player to directly perceive the effect of the antibiotic on the number of living cells. The right panel displays three different views of the current best living cell. Two of them represent its genome, with either the transcribed (top left) or translated sequences (top right). The third one (bottom) shows its phenotype (in green) including the resistance traits (for clarity

Figure 3: Screen capture of the Aevol game. The left panel presents bacteria population with a color code indicating their fitness (red cells being the fittest and blue the least fit). It also presents the current concentration of the five antibiotics (here, *bacillicin* is given at a 80% dose). The right panel presents the fittest individual's transcriptome (top left), genome (top right) and phenotype (bottom). The phenotype is represented in polar coordinates (green surface) together with the target function (red curve) and the five resistance sub-functions (red triangles). Here, the fittest individual became resistant to *bacillicin* after less than 100 generations (but resistance is not high enough to be fixed yet). Finally, the phenotypes of all living cells are represented with blue lines, allowing an estimation of the population diversity.

and esthetic reasons,  $\Omega$  is displayed in polar coordinates). It also shows the environmental target (red curve), the optimal shapes for the five resistance traits (red triangles), and the phenotypes of all living cells (blue lines). This allows the player to estimate the resistance traits in both the best individual and the rest of the population and thus to detect clonal interference between the metabolic and the resistance genes.

### Behavior with an automatic player

Although the Aevol game was not developed to *study* but to *teach* the emergence of resistant traits, we show here the behavior of the model with a simulated player that delivers antibiotics in various automatic ways. This study enables to verify that the behavior of the model is realistic enough to be used to educate people. It is also important for teachers that can use it to prepare himself to comment the players' actions.

### Effects of antibiotic dose

For each antibiotic, the wild-type strain was given a constant antibiotic delivery  $\alpha$ , varying between 50% and 100%.

Each time the antibiotic treatment resulted in eradicating the bacterial population, a new infection was automatically triggered and the antibiotic treatment was momentarily stopped until the population grew over 1000 living cells (the carrying capacity of the environment being 1600 individuals). For each antibiotic and dosage, we conducted the simulation until the resistance trait was considered to be fixed in the population (i.e. the resistance of the best living cell was sufficient to make it resistant to a maximum antibiotic dose). We measured both the number of successes of the antibiotic (number of infections driven to extinction) and the number of elapsed generations before the resistance criterion was met.

Figure 4 shows that antibiotics cannot drive the infections to extinction for doses below 80%. The effect of antibiotic dosage is intuitively obvious: the higher the dosage, the higher the probability to eradicate the infection.

Figure 5 shows whether the resistance criterion is met and if so, how fast, depending on the dose. Three ranges of dosages can be distinguished by comparing figures 4 and 5. For  $\alpha < 60\%$  (low dosage), the treatment fails and no resistance is acquired, most likely because the fitness cost

Figure 4: Number of infections successfully cured, as a function of the antibiotics dosage  $\alpha$  (dashed curve: mean).

associated with the resistance mutation is too high compared to the benefit it confers. For  $60\% \geq \alpha \geq 80\%$  (intermediate dosage), the treatment also fails but resistance can be acquired, which confirms the risk associated with sublethal dosages. For  $\alpha \geq 85\%$  (high dosage), although the treatment succeeds several times, all populations eventually acquired resistance. Increasing dosage generally speeds up resistance acquisition, but the precise relationship is antibiotic-dependent. More experimental replicates with different random seeds and wild-types would be needed to test whether this effect is random, genome-dependent (i.e. dependent on the probability to find a favorable mutation in the genome) or antibiotic-dependent (i.e. dependent on the position of the resistance trait in  $\Omega$ ).

Figure 5: Number of generations elapsed before the resistance criterion was met, as a function of the antibiotics dosage  $\alpha$  (dashed curve: mean). For  $\alpha = 60\%$ , only *aevollicin* led to resistance. For  $\alpha = 65\%$ , 3 of the 5 antibiotics led to a resistance.

These first results validate the game as a realistic tool to educate people for a correct use of antibiotics. They show

that, in the model, bacteria can acquire resistance traits and that the time to fixation of these traits depends on the way antibiotics are used. Moreover, the behavior of the five antibiotics is globally coherent, with slight differences that complexifies the game.

### Effect of treatment timing

For each of the five antibiotics, the wild-type strain has been submitted to intermittent treatments (with a 100% dosage). The dose delivery randomly switches from treatment to non-treatment using a Poisson process with a switching probability ranging from  $1/2$  to  $1/11$  at each generation. In all cases, the mean antibiotic delivery over a long period of time is 50%. Figure 6 shows that the treatment timing has no effect on resistance acquisition. Similarly, there is no effect on the probability of success of the treatment (data not shown).

In contrast to the previous results, here the bacteria quickly acquire resistance in all cases (the maximum delay being 1318 generations) while, for the same mean dosage (50%), a constant treatment never leads to resistance acquisition. Besides, intermittent treatment leads to a mean of 4.3 defeated infections before the resistance is fixed, regardless of the frequency of switches<sup>2</sup>, while such a low dose could not eradicate the infection with a constant treatment. This is probably an indirect effect of the fluctuation of population size when the infection is treated in an intermittent way. Indeed, a constant treatment with low doses leads to a small but constant population size (around 650 individuals for a 50% dose). In contrast, an intermittent treatment leads to huge variations in the population size (see figure 7 for an example).

Population genetics theory states that in case of variations in the population size, the effective population size is given by the harmonic mean over time of the real population size. Here, for a mean switching probability of  $1/3$  and before any resistance trait acquisition, the population size varies between 1 and 1250 individuals (mean value around 350 individuals) but the harmonic mean of the population size (excluding the periods of infection when no antibiotic is delivered) is around 18 individuals! The high level of genetic drift can hence explain that resistant individuals (that generally also carry deleterious mutations) sometimes manage to reproduce, thereby favouring the spread of resistance. Moreover, when the treatment temporarily stops, the population can expand. As figure 2 shows, this leads to mutation accumulation in the population. Thus, intermittent treatments also increase the apparent mutation rate (although the spontaneous mutation rate remains constant), thus increasing the population diversity and hence favouring the emergence of

<sup>2</sup>The different antibiotics do, however, behave differently: *prokarycin* leads to 4 successes on average, *microbicin* 5.9; *bactericin* 7.6; *bacillicin* 3.3 and *aevollicin* 0.8. This is consistent with the previous section, *aevollicin*, in particular, being more prone to resistance traits acquisition.

resistant mutants.

Figure 6: Number of generations elapsed before the resistance criterion was met, as a function of the antibiotics treatment dynamics. The antibiotic treatment switches between on and off at each generation with a probability ranging from  $1/2$  to  $1/11$ . See figure 4 or 5 for the legend.

These differences between intermittent high dose treatment and constant small dose treatment (for similar mean) shows the importance of taking into account evolutionary effects like population bottlenecks and spatial expansion when dealing with antibiotic resistance.

### Effect of pharmacodynamics and adherence

In the first two experiments, the antibiotic dosage was either constant or piecewise-constant over time. However, in a real situation, the antibiotic delivery depends on many physiological parameters such as means of delivery and half-life of the drug. The Aevol game can be used to teach the effects of these parameters and to introduce a patient's adherence to the prescribed treatment in the model, that is, the fraction of scheduled doses taken. Indeed, it has been shown that adherence can have a strong influence on resistance emergence, at least during antiviral therapy (Rosenbloom et al., 2012). Here, we show the behavior of an antibiotic treatment with *bacillicin*. The drug was given to the patient at 40% doses with one dose every 9 generations (the maximum drug concentration still being 100%). Five percent of the drug was degraded at each generation (drug half-life: 21.5 generations).

Figure 7, top panel, shows how drug concentration evolves during a treatment with perfect adherence, and the resulting effect on the bacterial load. Since the evolutionary process is included in the simulation, we can study the influence of drug dynamics on the emergence of a resistant mutant in relation to the population expansion that occurs regularly during the antibiotic delivery. The game can also be used to show the impact of patient drug-taking behavior on the dynamics of both the bacterial population and emergence of resistant strains. Figure 7, bottom panel, shows

the drug concentration, bacterial population and resistance to *bacillicin* when the patient randomly misses one dose out of four. Here, after only two missed doses (doses 4 and 7), the infection duration (initially 68 generations) is substantially longer. This also increases the risk for resistance to emerge before the end of the treatment, which in the present case does happen. Note that the simulation presented here was specifically chosen to illustrate the emergence of resistance due to a bad adherence. However, systematic experiments have not been performed yet on this question and no conclusion can be taken at this stage.

Figure 7: Effect of pharmacodynamic (top panel) and adherence (bottom panel) on bacterial load and antibiotics resistance (see main text for details).

### Conclusion and future work

The Aevol game was used in real conditions during “La Nuit des Chercheurs 2012” (October 2012), one of the main public science events in France. The simulation ran for three hours using a beam projector, and around 40 people from 10 to 65 years old played with it (the game was also successfully tested with younger children but in a smaller audience). After playing with the game, visitors wandered around the place, discussed with other researchers, and came back later to see how the game evolved and possibly play again. The result was a clear success: during the whole event, the bacterial population progressively acquired resistance to the five antibiotics. By the end of the experiment, complex treatments had become mandatory to fight the infections. Visitors could witness that the misuse of antibiotics during their first attempts had strongly influenced the evolution of

the population in the long term and created the subsequent difficulty for the next players. This shows the importance of a global tracing of the game, allowing the players to visualize the effects of previous treatments and detect *a posteriori* those having succeeded and those resulting in resistance acquisition. This experiment also showed that the game cannot be used without a supervisor to explain the behavior of the population and provide a minimal basis of evolution and genetics.

Although preliminary, the Aevol game provides a proof of concept that life models can be used to teach people difficult but relevant scientific questions. It also opens the door to many new developments. First, although a game is not a model, it provides the opportunity to compare the simulated dynamics with what is observed in *in vivo* experimental evolution (Hindré et al., 2012). This will require a more precise model of antibiotic action on the cell and of antibiotic resistance traits. Second, there are ample opportunities for improvement of the game. An important direction would be to enable the player to browse the whole population (not only the best individual) and to visualize *a posteriori* the entire course of evolution, starting from the beginning of the antibiotic treatment. Antibiotic delivery can also be improved. Here the antibiotic dose is directly fixed by the player (figure 3). One may ask the player for a prescription (i.e. dose and scheduling of antibiotic uptakes) and include pharmacodynamics in the model. Moreover, in the current version, antibiotics are harmless for the patient and can be used at maximum dosage without deleterious effects. Adding such effects (which are well documented for this kind of drugs) will add complexity to the game. Finally, an island model can be introduced in the game. Different islands could represent different patients as well as the global environment, thus enabling complex infection dynamics and multi-player gaming (e.g. on the Internet).

## Abstract

This paper reconsiders Ashby’s framework of adaptation within the context of dynamical neural networks. Agents are evolved to behave as an ultrastable dynamical system, without imposing a priori the nature of the behavior-changing mechanisms, or the strategy to explore the space of possible dynamics in the system. We analyze the resulting networks using dynamical systems theory for some of the simplest conditions. The picture that emerges from our analysis generalizes the idea of ultrastable mechanisms.

## Introduction

Organisms change their behavior in an attempt to remain adapted to their interaction with the environment, in order to maintain their self-constitution. W. Ross Ashby developed a theoretical framework to understand operationally this tendency towards ultrastability in organisms (Ashby, 1960). His approach considered the role of what can be interpreted as proxies to the essential variables of the organism - variables that correlate with its physiological well-being and that are directly available to the organism (e.g., body temperature, sugar level, oxygen intake). A behavior is ultrasatable if it conserves the proxies to the essential variables of the organism within some physiological limits under changing conditions. This paper explores the nature of the dynamics of ultrastable systems in artificially evolved neural networks.

Ashby’s framework of ultrastability is still central to much of the work on adaptive behavior, but many of the details of the implementation in neural networks have not been studied in enough depth (Harvey, 2008). The mechanism of adaptation Ashby studied was hand-designed specifically to find stable agent-environment interactions during perturbations. There are two aspects of his original framework that we seek to re-examine. First, the process of adaptation depends on a strict separation between the parameter-changing mechanisms and the behavior-producing mechanisms. In doing so, it relies heavily on the stochastic, switch-like nature of the behavior-changing mechanisms. Second, the framework of adaptation treats the projection of the critical boundary on the space of internal dynamics of the agent as a function only of the constitution of the agent.

In this paper we ask: what are the agent-environment conditions that allow artificial evolution to find neural networks with ultrastable properties? And, what are some of the ways in which ultrastability specified at the behavioral level can be implemented dynamically at the neural network level? We are interested in how a dynamical system can explore the richness of its state space, navigating through the different regions of its phase-portrait. The goal of this paper is to analyze neural networks evolved to be ultrastable in an attempt to extend and generalize Ashby’s framework of adaptation.

## Ashby’s Ultrastable Mechanism

Ashby based his framework around the basic assumption that organisms change their behavior by learning, so that the later behavior is better adapted to their environment than the earlier. He distinguished between two kinds of nervous system activity: hardwired reflex and learned behavior. In his framework (Figure 1A), the agent ( $\mathcal{A}$ ) is defined by two subsystems:  $\mathcal{R}$ , responsible for the ongoing reflexive behavior; and  $\mathcal{S}$ , responsible for regulating the behavior of  $\mathcal{R}$ . There are also a set of variables,  $\mathcal{P}$ , that serve as proxies to the organism’s essential variables ( $\mathcal{V}$ ). The environment ( $\mathcal{E}$ ) is defined as a system whose variables affect the organism through coupling and which are in turn affected by it.

For the organism to survive, its essential variables ( $\mathcal{V}$ ) must be kept within viable limits (gray area, Figure 1B). The ‘constitutive viable region’ maps to an ‘internal viable region,’  $\mathcal{M}(\mathcal{V})$  (gray areas, Figure 1C). When the agent’s internal dynamics are inside this region, the essential variables are kept within viable limits. When the internal dynamics are outside this region, the agent-environment dynamics have an effect on the proxies to the essential variables of the system. When the proxies are outside the appropriate ranges for the organism, they introduce parametric changes in  $\mathcal{S}$ . The configuration of  $\mathcal{S}$  influences the agent-environment interaction through  $\mathcal{R}$ . Ashby proposed a step-function as a mechanism for  $\mathcal{S}$ . In Ashby’s view, adaptation occurs as the system randomly flips through the catalog of  $\mathcal{R}$  dynamics, until it stumbles across one that is stable for the current environment.

Figure 1: Ultrastable system (adapted from Ashby, 1960). [A] Architecture: Environments ( $\mathcal{E}_i$ ); agent ( $\mathcal{A}$ ); reactive system ( $\mathcal{R}$ ); system in charge of learning ( $\mathcal{S}$ ); and proxy for the essential variables ( $\mathcal{P}$ ). [B] Region of viability (gray area) over the agent's essential variables ( $\mathcal{V}_i$ ), defined by the agent's constitution. [C] Agent's state space ( $\mathcal{R}$  and  $\mathcal{S}$ ). Gray attractors and limit cycles depict autonomous dynamics of  $\mathcal{R}$ . Blue and green trajectories depict dynamics of the system when coupled to environments  $\mathcal{E}_1$  and  $\mathcal{E}_2$ , respectively. Gray areas depict the internal viable regions, according to  $\mathcal{M}(\mathcal{V})$ . The magenta trajectory represents the state of the system during adaptation.

### Behaviorally Ultrastable Dynamical System

This paper extends the framework of ultrastability by reconsidering it from a behavioral level. There are two aspects of Ashby's framework that we re-examine.

First, in Ashby's mechanism and the more recent simulation models that have stemmed from his work (Di Paolo, 2000; Iizuka and Di Paolo, 2008; Herrmann et al., 2004), there is a strict division between the parts of the system that continuously interact with the environment, and the parts that change the internal organization of the system itself. As with previous work on modeling learning without synaptic plasticity (Yamauchi and Beer, 1994; Izquierdo et al., 2008), we consider a broader definition of an ultrastable system by removing the *a priori* distinction between the reactive and the learning components within the agent (Figure 2A). This allows us to explore some of the ways in which ultrastability specified at the behavioral level can be implemented at the neural network level.

Second, in Ashby's framework, the internal viable region (gray areas, Figure 1C) is a function  $\mathcal{M}(\mathcal{V})$  solely of the constitutive viable region (gray area, Figure 1B). When coupled, the agent-environment produce a dynamic which is specific to that environment (blue trajectory, Figure 1C). A change of environment modifies the coupled dynamics (green trajectory in the back, Figure 1C), but not the internal viable region. Therefore, a change in the agent-environment interaction can drive the internal dynamics of the agent outside its internal viable region, triggering changes in  $\mathcal{S}$  (magenta trajectory, Figure 1C), until a new coupled dynamic is found (green trajectory in the front, Figure 1C). This perspective is problematic because it assumes the internal dynamics of the agent must be within the same internal vi-

Figure 2: Extended ultrastable system. [A] Architecture: Environments ( $\mathcal{E}_i$ ); agent ( $\mathcal{A}$ ); internal dynamics ( $\mathcal{DS}$ ); and proxy for the essential variables ( $\mathcal{P}$ ). [B] Region of viability (gray area) over the agent's essential variables ( $\mathcal{V}_i$ ). [C] Agent's state space ( $\mathcal{A}$ ). Gray attractors and limit cycles depict the autonomous dynamics of  $\mathcal{A}$ . Blue and green trajectories depict the dynamics of the system when coupled to environments  $\mathcal{E}_1$  and  $\mathcal{E}_2$ , respectively. Colored volumes represent the internal viable regions,  $\mathcal{M}(\mathcal{E}, \mathcal{V})$ , colored according to the environment. Magenta trajectory represents the state of the system during adaptation.

able region for the two different behaviors. We consider a broader condition (Figure 2), where the internal viable region is a function of both the constitutive viable region and the environment,  $\mathcal{M}(\mathcal{E}, \mathcal{V})$ . Like in Ashby's case, we assume the constitutive viable region is defined over the essential variables by the organization of the organism (Figure 2B). However, when the organism is situated, the internal dynamics required to maintain the essential variables within their viability constraint changes as a function of the environment (blue and green regions, Figure 2C).

The picture of ultrastability in a dynamical system that emerges is different from Ashby's and subsequent models (Figure 2C). Assume a certain dynamics of the autonomous agent is suitable to maintain its essential variables within their viability constraints for a certain environment,  $\mathcal{E}_1$ , such that the coupled agent-environment interaction (blue trajectory) remains within the internal viable region (blue volume). Assume also a change to the environment,  $\mathcal{E}_2$ , such that the agent dynamics required to survive is different from the previous one (green volume). If the new coupled dynamics fall outside the new internal viable region, the agent's viability is threatened, setting off the proxies to the essential variables. The proxies drive the organization of the system towards an exploratory regime (magenta trace), until the behavior regains viability. The system regains viability by finding an internal dynamic that when coupled to the environment remains within the internal viable region.

In this view, a behaviorally ultrastable system must have three properties: (1) a rich reservoir of autonomous dynamics; (2) an exploratory regime capable of navigating the repertoire of autonomous dynamics; and (3) the ability to integrate those two regimes by modulating some aspect of the system via the proxies to the essential variables.

## Methods

We propose to study ultrastability by studying a simplified version of the extended view described above. We take for granted the self-constitution of the agent and the existence of a viability region. We also abstract away the agent-environment interaction. We assume the existence of  $N$  different environments such that, when combined with the agent's viability, they produce a series of internal viable regions. The organism is modeled as a network of  $N$  interacting neurons with  $C$  constrained ones and one proxy to the essential variables that can affect the whole network. The constrained neurons, in interaction with the environment, determine the state of the proxy to the essential variable. We artificially evolve these simple neural networks to maintain their proxies to the essential variables within viable ranges.

**Neural network** We used continuous-time recurrent neural networks (CTRNNs) as a model of the organism's internal dynamics. Each component in the network is governed by the following state equation (Beer, 1995):

$$\tau_i \dot{y}_i = -y_i + \sum_{j=1}^N w_{ji} \sigma(g_i(y_j + \theta_j)) + I_i \quad (1)$$

where  $y$  is the activation of each node,  $\tau$  is its time constant,  $w_{ji}$  is the strength of the connection from the  $j$ th to the  $i$ th node,  $g$  is a gain term,  $\theta$  is a bias term,  $\sigma(x) = 1/(1 + e^x)$  is the standard logistic activation function,  $I_i$  represents the external input to the neuron, and  $N$  represents the number of nodes in the network. The model does not include any form of synaptic plasticity mechanisms.

**Agent-environment interaction** For an adaptive organism, different environments are likely to require different internal dynamics. We abstract the agent-environment interaction by imposing arbitrary 'internal viable regions' over the neuron output space. Each of those regions is considered adaptive to a particular environment. That is, the dynamics available within this region of the phase-portrait are capable of maintaining the essential variables of the organism within their viability constraints. For simplicity, each environment is associated with one of the corners of the output space of the constrained neurons. The agent is considered adapted to the environment if its state in neural output is a distance less than 0.49 away from its corner.

**Proxy to the essential variable** According to the idealized rules above, at any point in time the agent can be adapted ( $a = 0$ ) or unadapted ( $a = 1$ ) to the environment. When the agent is adapted, the proxy to the essential variable rests at 0.0. When the agent is unadapted, the proxy to the essential variable increases over time, until it reaches one, according to the following state equation:  $\tau \dot{E} = -E + a$ . The proxy to the essential variable can affect the neurons

via the external input via a set of weights:  $I_i = gw_i E$ . In one of the experiments, we allowed for the proxy to the essential variable to modify the gain parameter instead:  $g_i = g_i + sw_i E$ , which is otherwise set to 1.

**Evolutionary algorithm** The parameters of the model were evolved using a real-valued genetic algorithm (Bäck, 1996). The optimization algorithm was run for populations of 100 individuals. We evolved the following parameters (ranges are shown in brackets):  $\tau_i$  [1, 10];  $w_{ji}$ ,  $\theta_j$ , and  $sw_i$  [-10, 10];  $gw_i$  [-0.5, 0.5]. Parameters were encoded in a vector of real-values between [-1, 1] and linearly mapped to their corresponding ranges. Each time the algorithm was run, individuals were initialized by random selection from the range of each parameter. Populations were seeded with center-crossing networks (Mathayomchan and Beer, 2002). At the end of a run, the parameters of the best performing individual were stored for later analysis.

**Fitness evaluation** Network activity is initialized to 0.0 once at the beginning of a trial. During a fitness trial, the environment changes to a new one every 200 units of time. The fitness of a trial is measured as the integral of the adapted variable over time.

$$f = \frac{\int_{t=0}^{200} w(t) (1 - a(t))}{c \int_{t=0}^{200} w(t)} \quad (2)$$

where  $t$  is time,  $a(t)$  is the binary adapted variable. The contribution of the adapted variable is weighted over time for each environment with a power function of time,  $w(t) = t^2$ , such that unadaptedness immediately after a change of environment weighs less than unadaptedness later on. Finally, in order to minimize the use of the critical boundary within the dynamics of stability, fitness is penalized for the number of times the agent becomes unadapted within a trial,  $c$ . The final fitness of a circuit is the average over all trials.

**Incremental evolution** The network is faced with two problems of a different nature. The first, to evolve attractors in each of the adapted regions, such that the network can stay within the adapted boundaries. The second, to transition between these regions. To allow for incremental evolution we divided the task into two stages. First, a minimal transition stage, where the network is asked to move from one environment to another one, always in the same sequence. Populations that are successful in this stage, move on to a second stage, where the network is asked to transition from any one environment to any other one, in random sequence.

**Alternative fitness evaluations** The fitness function defined above is based on the overt behavior, not the internal mechanisms of the circuit. In a final set of experiments, we use two fitness functions defined more mechanistically.

First, a function that maximizes the number of attractors in the phase-portrait. The network is started at different parts of the output space ( $3^C$  starting points that cover the full range of the constrained neurons) and integrated for 100 units of time. The fitness is calculated according to:  $f_a = (k/2^C)^5$ , where  $k$  are the number of attractors found in the circuit. The measure is normalized by the maximum number of attractors possible in the constrained circuit ( $2^C$ ). The proxy to the essential variable is fixed to 0 for this fitness evaluation. Second, a function that maximizes the area covered by a single dynamic in the phase-portrait. The network is started at one randomly chosen point in the output space and integrated for  $50 * 2^C$  units of time. The fitness is calculated by counting the number of corners of the constrained neural output space the circuit covers according to:  $f_b = (\sum_{i=1}^{2^C} m_i/2^C)^5$ , where  $m = 1$ , if the trace travelled near enough to the corner,  $d^* < 0.25$ , where  $d^*$  is the minimum distance to the corner in the full trajectory; otherwise  $m = 1.0 - ((d^* - 0.25)/0.75)$ . The proxy to the essential variable is fixed to 1 for this fitness evaluation. For this experiments, some of the ranges of the parameters were made larger:  $w_{ji}$ ,  $\theta_j$ , and  $sw_i$   $[-50, 50]$ , and  $w_{ii}$   $[4, 50]$ . When combined, the total fitness function was the product:  $f = f_a * f_b$ .

## Results

### 2D Ultrastability Task

**Two-neuron networks** The first set of experiments examined the ability of two-node CTRNNs to solve the simplest version of the ultrastability task: both neurons constrained (2C2N). In this task there are four possible environments, each with a respective internal viable region within the neural output space. The best two-node circuits attained a fitness of around 75%. That is, a typical successful network can only adapt to 3 of the four possible environments and transition between them in order (Figure 3). Evolutionary searches led to such networks 93 out of 100 times.

Figure 3: Neural traces during environment transitions for the 2C2N condition. Top two black traces represent neural output over time. Red trace represents the proxy to the essential variable. Black dashed vertical lines represent changes of environment. The environment is labeled at the bottom. Each environment is further divided by a red dashed vertical line into unadapted (no shade) and adapted (gray shade) stages.

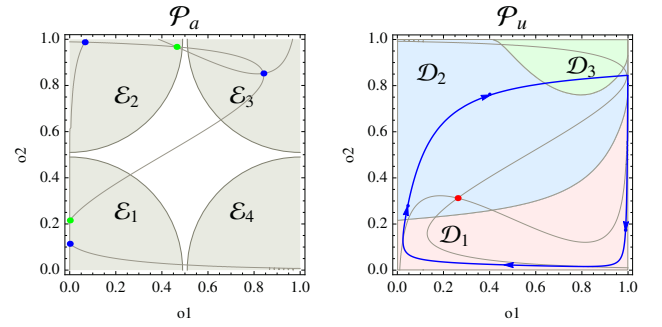

Figure 4: Phase portraits for the 2C2N condition. Adapted ( $\mathcal{P}_a$ ): stable equilibrium points (blue disks), saddle points (green disks), nullclines (solid gray curves), adapted regions for each environment (gray regions, labeled). Unadapted ( $\mathcal{P}_u$ ): unstable equilibrium point (red disk), limit cycle (blue trace). Basins of attraction of the adapted phase portrait are shown as colored volumes. The labels of the basins of attraction have a correspondence with the labels of the environments they are adapted to.

To understand the dynamics of the evolved circuit we analyzed the phase portraits of the most successful network when decoupled from the environment in the adapted and unadapted conditions independently by fixing the proxy to the essential variable to 0 or 1, respectively. The dynamics of a network are determined by the relative configuration of the nullclines. The network evolved three attractors (blue disks) in the phase portrait of the adapted condition ( $\mathcal{P}_a$ , Figure 4). The attractors cover three of the adapted regions (gray areas). In the unadapted condition, the network exhibits a limit cycle ( $\mathcal{P}_u$ , Figure 4). The basins of attraction, delimited by the saddle manifolds, of the attractors in the adapted phase portrait are visualized as light colored areas in the unadapted phase portrait. As can be seen, the limit cycle can transit between all evolved basins of attraction in the adapted phase. As we will see ahead, it is this combination of: (a) the shapes of the basins of attraction in the adapted phase portrait, and (b) the trajectory of the exploratory behavior in the unadapted phase portrait, that are crucial for the success of the adaptation.

To understand the limitations of the 2-neuron network, we need to understand how the proxy to the essential variable affects the dynamics of the network. A successful circuit needs two distinct types of dynamics: a rich repertoire of attractors, and a maximally exploratory dynamics. The maximum number of attractors in a circuit occurs when each nullcline intersects maximally. In the two node circuit, a limit cycle that can explore all the internal viable regions requires that the nullclines ‘fit’ inside of each other. There are other possible limit cycles in 2-neuron networks, but they don’t cover as much of the output space (Beer, 1995). The change in input to the neuron by the proxy to the essential variable

Figure 5: Parameter space for the 2C2N condition. Adapted phase ( $\mathcal{P}_a$ ). Unadapted phase ( $\mathcal{P}_u$ ). Regions of parameter that are crossed as the proxy to the essential variable,  $E$ , is gradually changed between 0 and 1 (brown line). Saddle node bifurcation (black curves). Hopf bifurcation (gray curves).

effectively shifts the nullcline up/down or left/right. A useful way to visualize this movement is in parameter space (Figure 5). The state of the proxy to the essential variable, by affecting the external input of the neurons, effectively moves the system through its parameter space. Different points in parameter space entail different dynamics. Crossing certain boundaries entails the system undergoing a bifurcation. Constrained to move in one direction in a line, the most successful circuits for this task evolve to navigate between a limit cycle and, at best, three stable attractor dynamics. From the limit cycle configuration, there is no way to shift both nullclines in one direction in a line to make them intersect maximally.

To understand the adaptive behavior of the coupled system, we need to understand the relationship between the shapes of the basins of attraction in the adapted phase portrait, and the trajectory of the exploratory behavior in the unadapted phase portrait. During a trial, the agent re-adapts to new environments by moving back and forth between the adapted ( $\mathcal{P}_a$ ) and unadapted ( $\mathcal{P}_u$ ) configurations. The timing of when the portraits change in relation to the basin boundary of the attractors is key to successful transitions. To illustrate this idea, we visualize the first transition of the trial shown in Figure 3, with the state of the network (brown trace) imposed over the changing phase-portrait (Figure 6). At the start of a run, the system starts off within the basin of attraction of the adapted environment ( $\mathcal{D}_1$ , Figure 4). The first time the environment changes, the proxy to the essential variable changes, the portrait of the system transitions towards the limit cycle configuration, and the state of the system begins to follow it ( $\mathcal{E}_2$ ,  $\mathcal{P}_u$ , Figure 6). When the system hits the boundary of the adapted region of the second environment, the proxy to the essential variable begins to return to normal, changing the portrait configuration back to the original ( $\mathcal{E}_2$ ,  $\mathcal{P}_a$ , Figure 6). Because the state of the system is now within the basin of attraction of the top-left

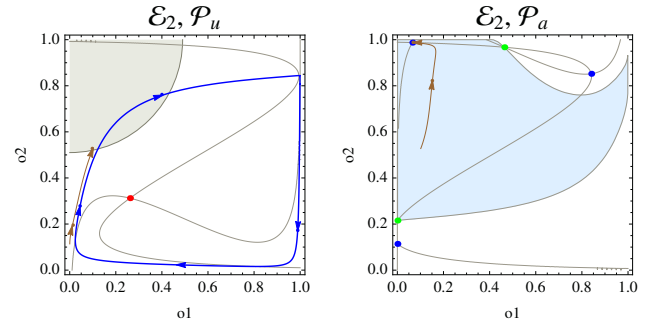

Figure 6: Neural activity (brown trace) in output space imposed over the phase portraits for the 2C2N condition. The two panels show the transition into  $\mathcal{E}_2$  (from  $\mathcal{E}_1$ ) from the example run in Figure 3. During the transition, the dynamics are first unadapted ( $\mathcal{P}_u$ ), then adapted ( $\mathcal{P}_a$ ).

attractor point, as soon as the limit cycle disappears, the system falls into it - effectively changing the dynamics of the system within the same configuration. A similar process occurs for each of the transitions.

The most successful 2-node networks displayed a similar dynamical configuration: (a) three equilibrium points in the adapted phase-portrait; (b) a limit cycle in the unadapted phase-portrait that allow them to transit between the basins of attraction of the adapted phase-portrait.

**Adding unconstrained neurons** One approach to obtain complete solutions to the 2-dimensional ultrastability problem is to increase the size of the network. This second set of experiments examined the ability of three-node CTRNNs to solve the same 2-dimensional version of the ultrastability task (2C3N). Same as before, there are four possible environments, each with a respective internal viable region within the neural output space of the two constrained neurons. The best three-node circuits attained a fitness close to 100%. Evolutionary searches led to successful networks (i.e., fitness greater than 98%) 38 out of 100 runs. A typical successful network was able to adapt to all four possible environments and transition between them in order (Figure 7). These successful networks can also transition successfully between any possible two regions. The networks use the output of the third unconstrained neuron (blue trace) to help them in both components of the task: (a) to have more attractors, and (b) to transition between them.

Similar to the two-neuron case, to understand the behavior of the network we can analyze the phase portraits of the dynamical system when decoupled from the environment in the adapted and unadapted conditions independently by fixing the proxy to the essential variable to 0 or 1, respectively (Figure 8). Analysis of a representative network shows four attractors in the phase portrait of the adapted condition (blue disks,  $\mathcal{P}_a$ ). The attractors cover each of the four adapted regions (gray volumes). In the unadapted exploratory condi-

Figure 7: Neural traces for the 2C3N condition. Neural output of the constrained neurons over time (black traces). Neural output of the unconstrained neuron (blue trace). Proxy to the essential variable (red trace). Changes of environment (dashed vertical lines). Environment labeled at the bottom. Each environment is further divided by a red dashed vertical line into unadapted (no shade) and adapted (gray shade) stages.

tion, the network exhibits a limit cycle (blue trace,  $\mathcal{P}_u$ ). The limit cycle begins to form as soon as the proxy to the essential variable becomes greater than 0.0, which simultaneously turns on the third neuron (bifurcation diagram not shown). Crucially, for the purposes of the ultrastable behavior, the limit cycle transits through all of the basins of attraction of the adapted phase portrait (colored regions). During the exploratory phase, as soon as the state of the system becomes adapted with respect to the current environment, the proxy to the essential variable goes back to normal, the exploratory portrait gives way back to the multiple attractor portrait, and the state of the system is contained within the basin of attraction of the currently adaptive configuration.

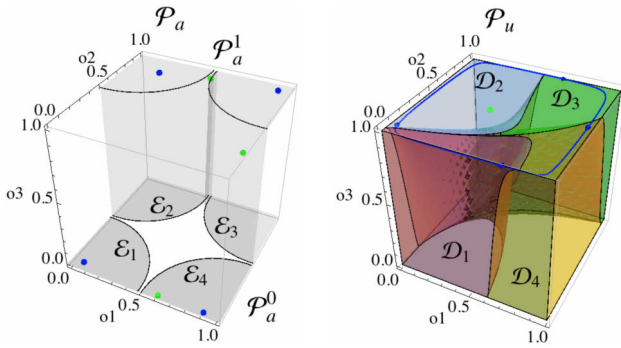

Figure 8: Phase portraits for the 2C3N condition. Adapted ( $\mathcal{P}_a$ ): equilibrium points (blue disks), saddle points (green disks), adapted regions for each environment (gray regions, labeled). The phase portraits can be divided into two depending on the output of the third neuron: off ( $\mathcal{P}_a^0$ ) or on ( $\mathcal{P}_a^1$ ). Unadapted ( $\mathcal{P}_u$ ): limit cycle (blue trace). Basins of attraction of the adapted phase portrait are shown as colored volumes. The labels of the basins of attraction have a correspondence with the labels of the environments they are adapted to.

Figure 9: Parameter space for the 2C3N condition. Movement (brown trace) from the unadapted dynamics ( $\mathcal{P}_u$ ) to the adapted dynamics ( $\mathcal{P}_a^0$ ,  $\mathcal{P}_a^1$ ). The additional neuron allows for the system to affect the system in two different directions. Saddle node bifurcation (black curves). Hopf bifurcation (gray curves).

This network overcomes the limitation of the 2-neuron network using the added dimension from the additional unconstrained neuron. To see how, we can re-interpret this system as a two-neuron network with two parameters: the proxy to the essential variable and the third, unconstrained neuron. We can visualize the different dynamics of the network in this two dimensional parameter space (Figure 9). When the proxy to the essential variable is at rest, and the unconstrained neuron is off, the system is in a two-attractor configuration ( $\mathcal{P}_a^0$ ). Like in the two-dimensional case, when the proxy to the essential variable moves away from the base, the nullclines of both neurons shift in one direction in a line, moving the organization of the system towards a limit cycle configuration ( $\mathcal{P}_u$ ). From the same original configuration, leaving the proxy to the essential variable at rest, but activating the third neuron, moves the system in a different direction ( $\mathcal{P}_a^1$ ). Therefore, adding unconstrained components allows the nullclines of the constrained neurons to shift in multiple ways. Ultimately, from the limit cycle configuration, depending on the state of the third neuron, the system can transition to different regions of parameter space (brown lines) until it finds an internal viable region for the current environment.

**Modifying neuron gains** There are variations to the model that can overcome the limitations of the 2-neuron network. These variations are possible when the proxy to the essential variable can affect parameters other than the external input. This is an interesting condition to consider because recent work in neuroscience has shown how neuromodulators can modify the intrinsic properties of neurons (Marder and Thirumalai, 2002). For example, when the proxy to the essential variable is allowed to affect the gain of the circuit ( $g_i$  in Eq. 1), rather than the input, then it is possible to evolve a 2-neuron network that can adapt to all four environments, and transition between each of them. The

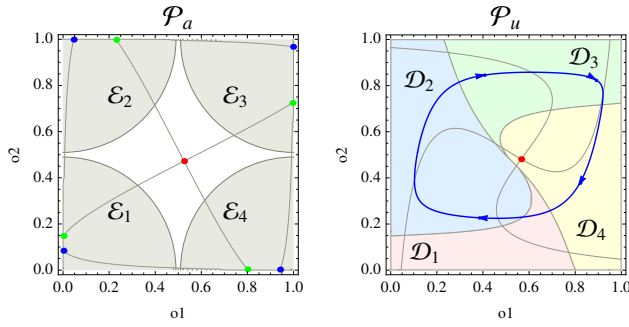

Figure 10: Phase portraits for the 2C2N where the proxy to the essential variable can affect the gains of the neurons. Adapted ( $\mathcal{P}_a$ ) and unadapted ( $\mathcal{P}_u$ ). The limit cycle in the unadapted phase-portrait transits all the basins of attraction of the adapted phase-portrait.

system easily changes between four attractors and a limit cycle (Figure 10). Change in the gain causes the nullclines to ‘twist.’ With this kind of modification available, it is possible for a system to change between the limit cycle configuration, where the nullclines are ‘fit’ inside each other, and the maximal-attractor configuration, where the nullclines intersect maximally, by ‘twisting’ the nullclines until they intersect the two other branches of the other nullclines.

### Ultrastability in Higher Dimensions

Evolving networks within the current restrictions of the task (i.e., internal viable regions in the corners of the neural output space) and model (i.e., proxy to the essential variable modifying only the external inputs) proved to be rather difficult for higher dimensions of the task. There are three tasks a behaviorally ultrastable system has to accomplish. First, it must maximize the number of attractors. Second, it must have access to a cyclic attractor that maximizes the coverage of its state space. Third, it must integrate the two dynamics so as to solve the ultrastable task. We designed a series of experiments to identify which of those tasks becomes harder in higher dimensions.

First, we tested each of the tasks individually, by directly evolving networks to either maximize the number of attractors or to maximize the area covered by network’s activity in output space. It was relatively easy to evolve larger networks to have the maximum number of attractors in their portraits. For example, after 5000 generations, 9 out of 10 circuits evolved successfully ( $> 99\%$  fitness) on the 5C5N task (i.e., 5-neuron network with 32 attractors). Similarly, it was easy to evolve larger networks to have dynamics that maximized the coverage of their output space. For example, after 5000 generations, 5 out of 10 circuits evolved successfully ( $> 99\%$  fitness) on the 5C5N task (i.e., a 5-neuron network with a single dynamic that allowed it to travel through all 32 corners of the neural output space). As far as we can

Figure 11: Phase portraits for the 3C5N condition. Projections in 3-dimensional space of the 5-dimensional phase portraits. Both adapted and unadapted portraits are shown in the same projection. The adapted portrait ( $\mathcal{P}_a$ ) contains 8 attractors in the corners (blue disks) and 8 saddle points (green disks). The unadapted portrait ( $\mathcal{P}_u$ ) contains one limit cycle (light blue trace) that transits close enough to all corners.

tell, the individual tasks scale well to higher dimensions.

We then tested evolving agents using the combined fitness function: one component to maximize the number of attractors while the proxy to the essential variable is set to 0 and another component to maximize the area covered by network’s activity in output space while the proxy to the essential variable is set to 1. We performed 50 evolutionary runs for 3C3N, 3C4N, and 3C5N tasks. We found no solutions for 3-, and 4-neuron networks. We found 4 out of 50 successful ( $>99\%$ ) 5-neuron networks. These results suggest the difficulty is in the integration of the two distinct behaviors.

As expected, the successful networks had 8 attractors in the adapted condition (blue disks, Figure 11), and an intricate cycle in the unadapted condition that passed relatively close to all the attractors (light blue trace, Figure 11). Due to the higher dimensionality, analyzing the basins of attraction of this network and their relationship to the limit cycle was not attempted. These networks were only partially successful because although they integrate the two tasks, when tested on the ultrastable task, they do not always transition successfully between all possible environments.

A number of key challenges remain to be studied. It will require further analysis to understand the difficulties encountered in higher dimensions. A few things to consider are: (1) adding unconstrained neurons; (2) further analyzing the dynamics of the partial solutions; and (3) using alternative arrangements of the internal viable regions.

### Discussion

This paper analyzes the dynamical possibilities for mechanisms of adaptation in living organisms based on Ashby’s framework of ultrastability. To explore alternative mecha-

nisms to the ones studied by Ashby and subsequent works, we developed evolutionary conditions that selected for behaviorally ultrastable systems. We analyzed the resulting neural networks using dynamical systems theory for the simplest conditions. The picture that emerged from our analysis opens up the idea of ultrastable mechanisms to a broader set than the original. It also allows for a more concrete instantiation of the framework within the context of neural networks.

The analysis in this paper was purposefully limited to the smallest networks in the lowest dimensional conditions. It's not hard to generalize our re-interpretation of ultrastable systems to higher dimensions. A system with many neurons can have a vast set of internal viable regions. The regions can form intricately connected networks in the high-dimensional output space. The proxies to the essential variables shift the rich repertoire of dynamics into the exploratory configuration, allowing the network to transition between different internal viable regions. The dynamics of exploration can be richer than just limit cycles, including for example chaotic dynamics. Re-adaptation corresponds to shifts in the phase portrait configuration: out of the exploratory regime, back into the rich dynamical repertoire. Crucially, in any one system, it is possible that only a fraction of the internal viable regions are explored during its lifetime, depending on the environmental changes experienced. In this view, the co-development of a rich dynamical repertoire together with a sufficiently encompassing exploratory dynamic occurs over evolutionary timescales, endowing agents with richer ultrastable systems to increase their probabilities of re-adaptation to novel environments.

Although the simplified 'internal viable regions' used in this study makes for tractable initial analysis, there are a number of conceptual variations not considered in this paper that are easily conceivable within the same framework. First, the shape and location of the region that is adaptive for any one environment can be any, not just the corners. Second, an internal viable region can contain more than one attractor, the boundaries of the region delimited by their combined basins of attraction. Third, internal viable regions for different environments can overlap. A simple re-interpretation of some of the networks analyzed in this paper could illustrate any of these variations. Interestingly, one idea that follows immediately from having richer internal viable regions is that which attractor within the region an agent finds itself in will depend on its history of interaction with the environment. Ultimately, the idea for this framework is to use internal viable regions defined by the actual interaction between an agent with certain essential requirements for its constitution and the environment.

The framework of behavioral ultrastability proposed in this paper could be developed further to study habit formation. In this paper, agents are evolved first to transition between environments in a specific order, and once successful, to transition between any possible environment. In both con-

ditions, the history of agent-environment interactions does not contain additional information about the likeliness of the next possible environment. An interesting space of solutions to study would be agents evolved to cope with a subset of all possible sequences of transitions. Changes from one sequence of transitions to a different sequence could involve a second level of adaptation, where the exploratory dynamics changes as a function of the sequence experienced. This would allow for the study of mechanisms with slower time constants that keep track of the sequence of transitions to modulate the exploratory dynamics.

## Abstract

Gene regulatory networks (GRNs) represent the interactions between genes and gene products, which drive the gene expression patterns that produce cellular phenotypes. GRNs display a number of characteristics that are beneficial for the development and evolution of organisms. For example, they are often robust to genetic perturbation, such as mutations in regulatory regions or loss of gene function. Simultaneously, GRNs are often evolvable as these genetic perturbations are occasionally exploited to innovate novel regulatory programs. Several topological properties, such as degree distribution, are known to influence the robustness and evolvability of GRNs. Assortativity, which measures the propensity of nodes of similar connectivity to connect to one another, is a separate topological property that has recently been shown to influence the robustness of GRNs to point mutations in *cis*-regulatory regions. However, it remains to be seen how assortativity may influence the robustness and evolvability of GRNs to other forms of genetic perturbation, such as gene birth via duplication or *de novo* origination. This abstract outlines a recent publication, in which we employed a computational model of genetic regulation to investigate whether the assortativity of a GRN influences its robustness and evolvability upon gene birth. We considered GRNs to be robust if they conserved all their phenotypes (attractors) following the introduction of a new gene, and evolvable if they were able to innovate at least one novel phenotype. We found that the robustness of a GRN generally increases with increasing assortativity, while its evolvability generally decreases (Figure 1; above), and this results in an increased proportion of assortative GRNs that are simultaneously robust and evolvable (Figure 1; below). This is due to: (1) Assortative GRNs have shorter attractors, which are more likely to be conserved (Figure 2), and (2) assortative GRNs have smaller out-components, resulting in a reduced chance of innovation (Figure 3). This work extends our understanding of how the assortativity of a GRN influences its robustness and evolvability to genetic perturbation.

Figure 1: Proportion of GRNs with set conservation, innovation, or both as a function of assortativity. (Above) Light gray bars show the proportion of GRNs at a fixed assortativity value that exhibited set conservation after gene birth. Medium gray bars represent the proportion that exhibited innovation. Dark gray bars show the overlap, which is the proportion that both conserved and innovated. Each bar is a proportion of 5000 GRNs for each of:  $\bar{k}_{out} \in \{1.3, 2.0, 3.0, 4.0\}$  and 9 assortativity values. (Below) The proportion of the overlap is shown at a zoomed-in scale. Note that total proportions of conservation and innovation may not add up to 1, as some GRNs may exhibit neither. The percentage change from the smallest to the largest assortativity value is shown for conservation, innovation, and both. Statistical significance for Spearman's correlation is denoted by \* ( $p < 0.05$ ), \*\* ( $p < 0.01$ ), or \*\*\* ( $p < 0.001$ ). Vertical dashed lines show the minimum and maximum assortativity values for the middle 95% of the null distribution for each  $\bar{k}_{out}$ .

\* Published in Journal of Theoretical Biology, 2013, <http://dx.doi.org/10.1016/j.jtbi.2013.03.019>

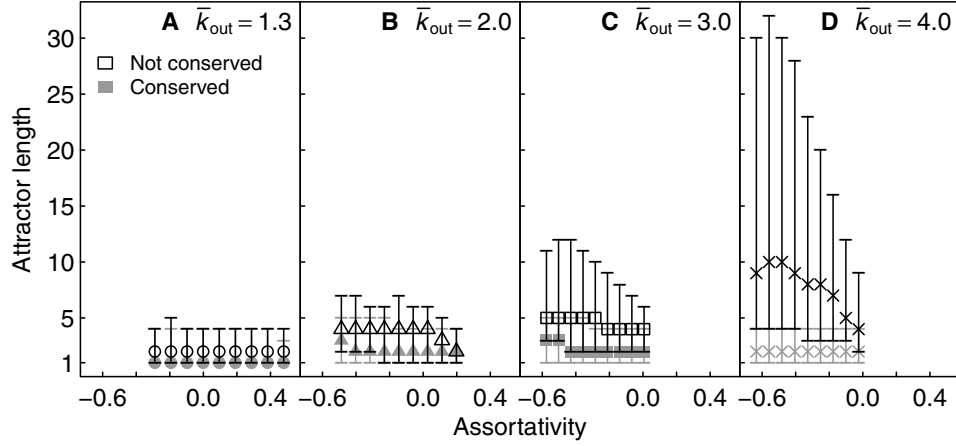

Figure 2: Lengths of attractors that were or were not conserved as a function of assortativity. Each point represents the median length of unique attractors before gene birth in 5000 GRNs at a fixed assortativity value. Error bars represent the 25<sup>th</sup> and 75<sup>th</sup> percentiles. Medians and percentiles for attractors that were not conserved are shown in black, whereas those for attractors that were conserved are shown in gray. GRNs are grouped according to their  $\bar{k}_{out}$  and assortativity value, as in Figure 1. Conserved attractors are significantly shorter for every assortativity value and every  $\bar{k}_{out}$  (Wilcoxon Rank Sum test,  $p \ll 0.001$ ).

Figure 3: Proportion of innovation as a function of the out-degree of the newly introduced node, and whether the new node possesses a large or small out-component (OC). The OC of a node  $i$  in the GRN is the set of nodes in the GRN that is reachable via directed paths starting from  $i$ . The 5000 GRNs at the highest assortativity value for each  $\bar{k}_{out}$  were first binned by the out-degree of the new node, since this property positively influences the ability of the new node to cause innovation. Each out-degree bin was then split into two groups according to whether the new node possesses a large OC (larger or equal to the median OC size) or small OC (smaller than the median OC size). Black markers represent the proportion of GRNs that innovated at least one attractor where new nodes possess large OCs, and gray markers represent innovation for GRNs where new nodes possess small OCs. Asterisks mark significant differences in proportions between large and small OC categories ( $p < 0.05$ , Pearson's chi-squared test). Only out-degrees for which at least 30 GRNs were present in large and small OC bins are plotted.

Complex networks are ubiquitous and known to profoundly affect the processes that take place on them. From a theoretical perspective, some of the most complex processes studied to date, occurring on complex networks, are related with behavioural dynamics and decision-making, often described by means of social dilemmas of cooperation. Among these, the Prisoner's Dilemma (**PD**) provides the most popular metaphor of such dilemmas, given that its only Nash equilibrium is mutual defection, despite mutual cooperation providing higher returns – thus the dilemma. We may also assume a population dynamics (evolutionary) approach to game theory where agents revise their behaviour based on the perceived success of others, creating a gradient of selection which dictates how cooperation self-organizes through time. Evolutionary Games provide one of the most sophisticated examples of complex dynamics in which the role of the underlying network topology proves ubiquitous. For instance, when cooperation is modeled as a prisoner's dilemma game, cooperation may emerge (or not) depending on how the population is networked (Santos et al., 2012a).

Up to now, it has been hard to characterize in detail the global dynamics by which local self-regarding actions lead to a collective cooperative scenario while relating it to the network topology. Indeed, most network studies have been focused on the analysis of the evolutionary outcome of cooperation – either by means of the numerical analysis of steady states or by the analytical determination of the conditions that lead to fixation – without characterizing the self-organization process by which one of the strategies outcompetes the other. Here we report on new results (Pinheiro et al., 2012a,b; Santos et al., 2012b,a), where we show how to establish the link between individual and collective behavior in the context of evolutionary games in networked populations.

Overall, we show how behavioral dynamics of individuals facing a cooperation dilemma in social networks can be understood as though individuals face a different dilemma in absence of structure. As illustrated in Fig. 1, homogeneous networks promote a coexistence dynamics between cooperators and defectors – akin to the Chicken or Snow-

drift game – whereas heterogeneous networks, from single to scale-free networks, favor the coordination between them, similar to the Stag-hunt game. In other words, while agents locally perceive and play a **PD**, globally the dynamics of the population resembles the one obtained from a completely different game, as if, individuals would be locally facing a different dilemma.

To this end we define a time-dependent variable – that we call the average gradient of selection (**AGoS**) – and use it to track the self-organization of cooperators when co-evolving with defectors. In finite well-mixed populations, that is, populations in which every individual can interact with every other individual in the population, this gradient of selection ( $G(x_C) = T^+(x_C) - T^-(x_C)$ ) can be computed analytically, as the difference of the probabilities of increasing ( $T^+(x_C)$ ) and decreasing ( $T^-(x_C)$ ) the number of cooperators, for each fraction  $x_C$  of cooperators. While this quantity is impossible to be attained analytically for arbitrary network structures, the **AGoS** provides a numerical account of the same variables, offering the change in time of the frequency of cooperative traits under selection. The **AGoS** can be computed for arbitrary intensity of selection, arbitrary population structure and arbitrary game parameterization. We further prove that the global games are not fixed: they change in time, co-evolving with the motifs of cooperators in the population. The evolutionary outcome of such a self-organization process will depend sensitively on this co-evolution, which can be followed using a time-dependent **AGoS**.

The scenarios illustrated in Fig. 1 become even richer whenever one takes into account the role of selection pressure (also known as intensity of selection) in the overall evolutionary dynamics of a networked population. Selection pressure provides the relative significance of agent fitness in the evolutionary process, as opposed to an arbitrary or random adoption of strategies. This is important, as selection pressure can be very different depending on the processes at stake. Indeed, in many social interactions, errors in decision making, perhaps induced by stress or exogenous confounding factors, which often translate into a bounded rational be-

Figure 1: The Average Gradient of Selection (AGoS) provides a characterization of the change in time of the fraction of cooperators under natural selection, being positive (negative) when the fraction of cooperators tends to increase (decrease). While in well-mixed populations (left panel), the tragedy of the commons ( $x_c = 0$ ) emerges as the only stable fixed point, homogeneous networks favor the co-existence of cooperators and defectors (middle panel), whereas degree heterogeneous networks (right panel) creates two basins of attraction, as if agents would be locally facing a coordination dilemma.

haviour of the players, may lead to an overall weak selection environment. This contrasts with many other situations where selection is mainly strong such as the dynamics of cultural evolution. Moreover, the fate of cooperation in social networks may depend on how the success of the others is locally perceived, which is related with the number of partners of each player and their social context, turning selection pressure into a central variable in behavioural evolution.

As we show in (Pinheiro et al., 2012b), as opposed to what happens in heterogeneous populations that generate a coordination dynamics for a broad range of selection pressure values, on homogeneous networks the population-wide dynamics depends on the intensity of selection: under strong selection they favour a co-existence like dynamics while under weak selection we recover the *well-mixed* scenario of a **PD**-like dynamics which leads to the demise of cooperation (Fig. 1, left panel). Additionally, we were able to identify the existence (on several types of networks) of an optimum level of selection pressure for which cooperation is maximised. The underlying process that leads to this result differs from homogeneous to heterogeneous networks. In the first class of networks the optimal selection pressure is associated with the ability of cooperators to form and sustain clusters, while on the second class it is the result of a decoupling in the distribution of intensities of selection between pairs of agents that is present from the natural diversity of fitnesses (Santos et al., 2012a) in the population.

Additionally, the application of the AGoS is not limited to 2-person games. In fact, as discussed in (Santos et al., 2012b), heterogeneous network structures create multiple internal equilibria when individuals face public goods

dilemmas, departing significantly from the reference scenario of a structureless population, approach which can also be extended to N-person games in adaptive networks (Moreira et al., 2013). Finally, we would like to stress that the scope and importance of this methodology goes far beyond the present application to evolutionary games on graphs. The principles can be used to extract any dynamical quantity that describes a process (as long as it is a Markov process) taking place on a network such as the outbreak of epidemics or the spread of information.

## Abstract

Complex multi-cellular organisms are the result of evolution over billions of years. Their ability to reproduce and survive through adaptation to selection pressure did not happen suddenly; it required gradual genome evolution that eventually led to an increased emergent complexity. In this paper we investigate the emergence of complexity in cellular machines, using two different evolutionary strategies. The first approach is a conventional genetic algorithm, where the target is the maximum complexity. This is compared to an incremental approach, where complexity is gradually evolved. We show that an incremental methodology could be better suited to help evolution to discover complex emergent behaviors. We also propose the usage of a genome parameter to detect the behavioral regime. The parameter may indicate if the evolving genomes are likely to be able to achieve more complex behaviors, giving information on the evolvability of the system. The experimental model used herein is based on 2-dimensional cellular automata. We show that the incremental approach is promising when evolution targets an increase of complexity.

## Introduction

Evolved artificial developmental systems' remarkable range of products, i.e. biological organisms, with variety in form, function and "complexity", all tailored to fill their niche, is an alluring design concept. Such bio-inspired design methodology can be used for any kind of system to create a variety of artifacts that can handle different problems.

However, knowledge and methods to be able to exploit similar core processes [14] for the design of artificial organisms are still subjects of exploration and research.

Evolved artificial developmental systems have shown many favorable features that are borrowed from natural biological systems, such as the main subject here, the ability to evolve inherent complexity as a response to evolutionary pressure [27]. Evolvable, or in particular EvoDevo systems are products of bottom-up processes, in contrast to typical top-down engineering design approaches. A system emerging as a product of a bottom-up process can target system properties out-of-bounds for traditional top-down designed artifacts. Self-organization, self-construction, adaptivity, scalability and robustness are all example of such hard to reach properties.

In contrast to the open ended evolution in nature, evolution of artificial EvoDevo systems often includes an expressed goal; fitness is a kind of usability [15] measurement. The target functionality is defined and thus placed within some

complexity measure. Such complexity can be defined at several levels. The complexity of the machine's composition, i.e. the number of components and connections can be quantified. Another complexity measurement may be functionality in terms of information processing. Quantification of complexity in artifacts and biological organism has no common defined unit of measurement or ratio of comparability. However, intuitively there are differences. Such differences can be related to the composition of artifacts/organisms or as a measure of their functionality. If complexity, for an organism, is a measurement of functional properties within its environmental niche, different levels of behavioral complexity can be said to exist. In this context, high complexity is not a goal in itself; it is merely a product of the species adaptation to be able to reproduce. The genetic information included in the genotype and the developmental processes for any particular specie has evolved and diverged through adaptation from the primordial soup. As such, the behavioral complexity of organisms is a product of the evolved interplay between genetic information and developmental processes.

As a step toward more knowledge of underlying processes and finding design methodologies for the exploitation of EvoDevo for artificial systems, we investigate how a gradual change in the complexity requirements, in evolutionary time, influence on EvoDevo system's ability to evolve complexity. Further, a variation of Langton's Lambda parameter [16] is used as an indicator of evolutionary genome adaptation to resulting phenotypic complexity. The taken experimental approach uses a kind of incremental complexity evolution to simulate the process of species adaptation to a changing environment requiring growth of complexity. A 2D cellular developmental model based on Cellular Automata (CA) is used in the experiments, so as to be able to visualize artificial organisms' development in 2 dimensions.

In our incremental evolutionary approach, the evolution process tackles the problem of targeting complexity incrementally. Instead of seeking for maximum complexity in the early generations, the problem is divided in sub-problems. Generations are divided in intervals and in every interval the target complexity demand is increased, keeping the target functionality unvaried, i.e. the class of problems is the same. In such way, it may be possible to evolve favorable genes for intermediate complexity levels, which may be beneficial in order to achieve higher complexity in the long term.

Since no universally accepted definition of complexity exists, many authors use it implicitly without specifying which

notion of complexity they are using. Yet, without any common measure of genotype or phenotype complexity, any significant claim is not verifiable. Genome complexity measures may sometimes be unfitting, since the amount of information encoded in the genome is not directly proportional to the complexity of the emergent organisms. Even in nature, some unicellular eukaryotic organisms have much larger genomes than humans. In addition, there are other factors that impact on the organisms' complexity during their growth, e.g. the environment.

One may argue that complexity of an EvoDevo system may be measured in terms of information contained in a genome, by ranking through a Turing machine, by quantifying the capacity for a genome to exploit a provided area of growth, using approximations of Kolmogorov complexity [5, 6, 9]. The used complexity measure is based on compression of CA behavior in terms of trajectory and attractor lengths, a kind of adaptation of principles from Kolmogorov complexity.

The article is laid out as follows: background information and motivation on incremental evolution is presented in Section 2. In Section 3 Lambda genome parameter is introduced and in Section 4 the developmental model used in the experiments is described. Section 5 explains the genetic algorithms used herein. The experimental setup is illustrated in Section 6 and in Section 7 the results of the experiments are presented together with a discussion of the ideas and the results. Finally Section 8 concludes the work.

## Incremental Evolution

A general evolutionary strategy may be too difficult for the evolution system to discover possible solutions directly. Instead, it is possible to learn complex behaviors incrementally, starting from a simple behavior and gradually making the task more challenging [1]. Incremental evolutionary approaches have been used successfully to evolve complex behaviors step by step. Many studies investigated the training of artificial neural networks with Genetic Algorithms (GAs), in order to evolve robots controller able to perform complex action sequences, e.g. complex light switching behavior [2] or robot duels controllers [3]. This approach has shown interesting results, being able to evolve converged populations to the new task. On the other hand, conventional evolutionary methods may have too high selective pressure in the early stages of the evolution, getting the GA blocked in an unfruitful area of the search space. If the population is first evolved to an easier behavior, it may be possible to discover and access a region of the solution space where even more complex behaviors are more likely to be found. As such, the ultimate complex behavior may be reached incrementally by evolving a sequence of intermediate behaviors with growing complexity:

Behavior 1  $\xrightarrow{\Delta}$  B 2  $\xrightarrow{\Delta}$  ....  $\xrightarrow{\Delta}$  B n-1  $\xrightarrow{\Delta}$  B n

In this way, genotypes are evolved gradually and the search is driven on solutions that are likely to benefit and retain existing capabilities. Conventional evolution tends to fluctuate between idiosyncratic but still not interesting solutions [12]. Incremental evolution may foster continuing innovation by elaborating on available solutions.

## Genome Parameter: $\lambda$

In our cellular developmental model, we are aiming to target complex phenotypic properties. Attractor length, i.e. development reaches a structure or state that is stable by self-regulation (point attractor) or a dynamic phenotypic structure that is self-reorganizing (cyclic attractor), is the chosen metric. The strategy is therefore to evolve intermediate genotypes that develop and express specific attractor lengths. Every fixed number of generations, we increase the sought attractor length value to increment the complexity demand.

In terms of evolvability, since we want to investigate if the evolving genotypes are able to evolve and develop more complex phenotypes, we attempt to measure the behavioral regime using a genome parameter. Parameters obtained from the genome information can be used to estimate the dynamic behavior of the system. In this work, the genotypes are represented as a transition rule table, where developmental actions are defined as a function of the neighborhood configuration (see next chapter for details). In this way, it is possible to analyze the different developmental actions and calculate parameters obtained from the genome table.

Several genome parameters have been previously proposed in order to measure genotype properties. Langton [16] studied a parameter  $\lambda$  as a measure of the activity level of the system and its disorder. A similar parameter, neighborhood dependent, is Absolute Activity presented by de Oliveira [20]. Li [21] introduced Mean Field Parameters to monitor if the majority of the regulatory actions follow the “mean” configuration. de Oliveira [20] presented a very similar parameter called Neighborhood Dominance. Binder [22, 23] introduced the Sensitivity parameter which measures the number of changes in the output of the transition table based on a change in the neighborhood, one cell at a time, over all the possible neighborhoods of the rule being considered. This has also being studied by de Oliveira [24, 20] as Context Dependence. Different properties of genome parameters have been investigated in details in [11]. In particular, the  $\lambda$  parameter has shown interesting abilities to discriminate genotypes in different behavioral classes, e.g. fixed, chaotic, random [13]. As such, we monitor the  $\lambda$  value along the evolutionary process.  $\lambda$  is calculated according to Equation 1.

$$\lambda = \frac{K^N - n}{K^N} \quad (1)$$

$n$  represents the number of transitions to the quiescent state (i.e. inactive or dead state),  $K$  is the number of cells types and  $N$  is the neighborhood size (see following section for details).

## Cellular Developmental Model

The developmental model used in this work is a minimalistic cellular developmental model based on cellular automata, similar to cellular models used in [25, 26, 19]. The system herein is close to the field of Morphogenetic Engineering [7], where the goal is “self-architecturing” systems. In embryomorph systems [8], the approach is based on embryogenesis: the self-assembly of myriads of cells starting from a single zygote which holds the complete genotype information.

**Fig. 1:** Developmental model with cyclic boundary conditions and von Neumann neighborhood configuration.

A CA can be considered as a developing organism, where the genome specifications and the gene regulation information control the cells' growth and differentiation. The behavior of the CA is then represented by the emerging phenotype, which is subject to size and shape modifications, according to the cellular changes along the developmental process. Such dynamic developmental system can show adaptation, self-modification, plasticity [18] or self-replication properties [17].

0	0	0	2	2	{0,1,2}
		:			:
2	2	2	2	2	{0,1,2}

**Fig. 2:** Developmental table with neighborhood configurations and relative developmental actions.

The model is based on a two-dimensional cellular automaton with cyclic boundary conditions, as shown in Figure 1. The number of cell types is set to three (type 1 and 2 plus the quiescent or dead cell type 0) in order to keep the property of multicellularity. A single cell (zygote) is placed in the centre of the development grid and develops according to a developmental table based on von Neumann's neighborhood (five neighbors). All the possible regulatory input combinations are explicitly represented in the development table, i.e. 243 ( $3^5$ ) neighborhood configurations.

To ensure that cells will not materialize where there are no other cells around, a restriction has been set: if all the neighbors of an empty cell are empty, the cell will be empty also in the following development step. This is represented in the first entry of the developmental table in Figure 2. A more detailed description of the development model is given in [10, 11].

## Genetic Algorithm

The Genetic Algorithm used in the experiments is tested with two different fitness functions: a classical fitness approach that

targets the maximum complexity and an incremental growth of fitness. An incrementally growing fitness denotes a changing environment that requires more complex behaviors to survive. It must be underlined that the two different fitness functions could in theory perform the same way. The same genotypes could be discovered through evolution since there are no restrictions in the areas of the search space that are being explored. Anyway, this is very unlikely to happen, since the environment is interpreted differently on the evolutionary time scale. The GA consists of a population of ten individuals and uses a roulette wheel technique for proportionate selection of two potentially useful individuals. The worst three elements are replaced by two new individuals that are copies of the two selected ones with mutation rate 0.02 for each of the entries in the developmental table. The third new element is generated by uniform one-point crossover of the two selected individuals.

As we mentioned, the main difference between the two evolutionary strategies lies in the fitness function. In the classical scenario, the fittest individual is the one with longest attractor length. In the incremental approach the fittest is the individual with smallest difference between the actual length and the target length in that specific generation, i.e. environmental requirements at specific moments in evolutionary time.

The target length is defined as follows: in the first generation it is set as 1, i.e. point attractor. In this phase, the GA searches for phenotypes that end up with a single point attractor. Every fixed number of generations, the target value is incremented by a constant value. It is expected that in the following interval of generations, the population will be able to evolve and adapt towards the new target, i.e. an increasing complexity demand for longer attractor length along the evolutionary timeline.

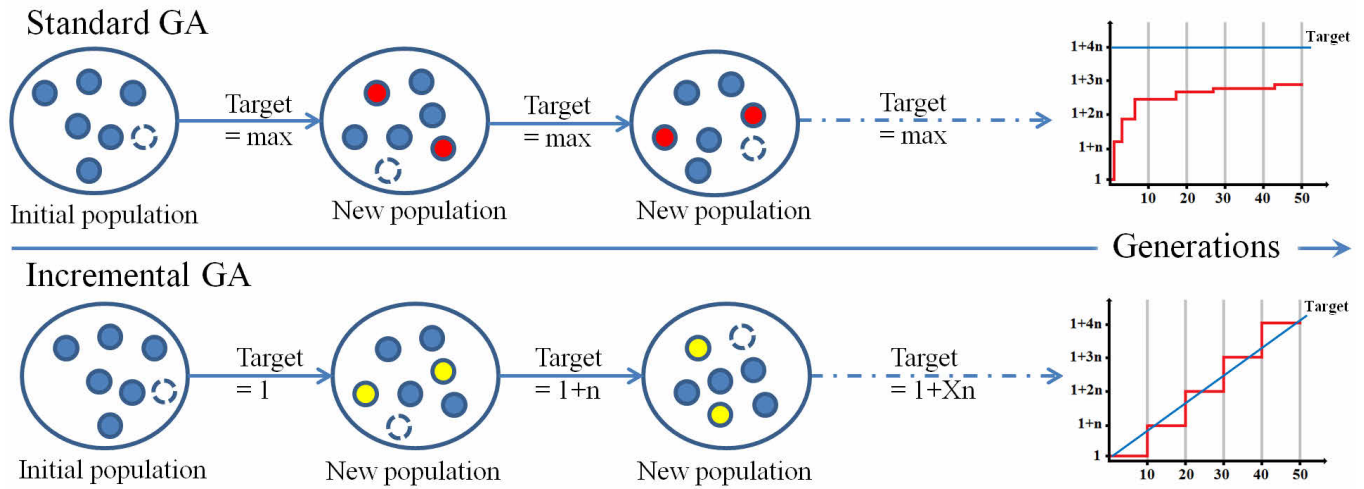

Details on the development process, number of generations, length of the intervals and initial conditions of the genotypes are given in the next section, which describes the experimental setup. Source code is available upon request.

## Experimental Setup

In the experiments herein, the main idea is to generate an initial population of ten genotypes, develop the corresponding phenotypes (starting from a single cell placed in the centre of the grid) until an attractor is found, evaluate the phenotypes with a fitness function and evolve the chosen genomes throughout the generations. This process is repeated for GA with standard fitness function and GA with incremental fitness function. The performances of the different algorithms are evaluated, measuring the ability to achieve sought complexity in terms of attractor length, i.e. number of development steps between two repetitions of the same state. This experimental setup is represented graphically in Figure 3.

Two different strategies of generating the initial population are investigated:

- From “dead genomes”: all the transitions in the developmental table lead to the dead state and the value of  $\lambda$  is uniform. In this scenario, the GA has to evolve “dead” genomes, i.e. the developed phenotype results in a dead

**Fig. 3:** Experimental Setup: GA with standard fitness on top (targeting maximum complexity), GA with incremental fitness on bottom (target fitness increased gradually)

organism after the first development step, towards “alive” genomes. This approach could be interesting since favorable genes are evolved from scratch, especially when random initialization is not possible or feasible.

- From random genomes: the initial population of genomes is initialized randomly<sup>1</sup>. In this way, it is possible to have extremely fit genomes, or very unfit, from the first generations. In both cases, it may be particularly difficult to evolve towards genomes with favorable characteristics to reach the defined goal. The parameter  $\lambda$  has a distributed value.

The way genomes are generated has a strong impact on how the resulting phenotypes will behave. Trying to understand the relation between genotypes and possible resulting phenotypes means understanding which kind of information is present in the genome and which behavioral properties may emerge. Since in our model all the possible regulatory combinations are fully specified together with the corresponding developmental actions, it is possible to calculate the Lambda genome parameter for each individual in the population.  $\lambda$  is calculated out of the regulative outcome in the developmental table, i.e. column  $C(t+1)$  in Figure 2. Following Langton’s definition [16], a quiescent state must be chosen. We choose the void cell type (type 0) as the quiescent state. Lambda is then calculated by  $1 - \text{the ratio between transitions to the quiescent state and the total number of transitions in the developmental table}$ . It is implicit that if the population is initialized with dead genomes, all the transitions in the developmental table will lead to the quiescent state. Thus,  $\lambda$  will be 0, which means genotypes with low behavioral activity. On the other hand, when the population is initialized with random genomes,  $\lambda$  is more likely in the vicinity of a critical behavioral regime, near the Edge of Chaos [16]. In this area of the solution space, it is more likely to find complex behaviors.

<sup>1</sup> Marsenne twister is used for initialization of randomized genotypes and genetic operators (mutation and crossover).

Monitoring Lambda along all the evolutionary process will give information on the ability of the population to evolve and adapt to the target complexity level.  $\lambda$ , as an indication of computation, has been discussed in [28]. However, from previous work [16, 11], we know that the attractor length of a certain organism is strongly related to its  $\lambda$  value, which can be calculated from the genome composition. As such, Lambda could be used to drive evolution in desired parts of the search space where the desired behavior is more likely to be found. This is part of ongoing experimentation.  $\lambda$  here is measured to gain information of the evolution of genome composition and interpreted as an indicator of the evolvability of the system, which may confirm our hypothesis that an increase in complexity is more likely to happen if evolutionary search leads towards the desired behavioral regime.

## Results and Discussion

In the experiments herein, the array size of the CA was set to  $4 \times 4$ . The size of the arrays was chosen as to be able to carry out experiments in reasonable computational time.

Organisms of  $4 \times 4$  cells may be considered rather small; however, the theoretical maximum attractor length is  $3^{16}$ . As such, even at the chosen array size, the number of development steps to reach an attractor could be rather big.

### Experiment 1: Dead Genomes

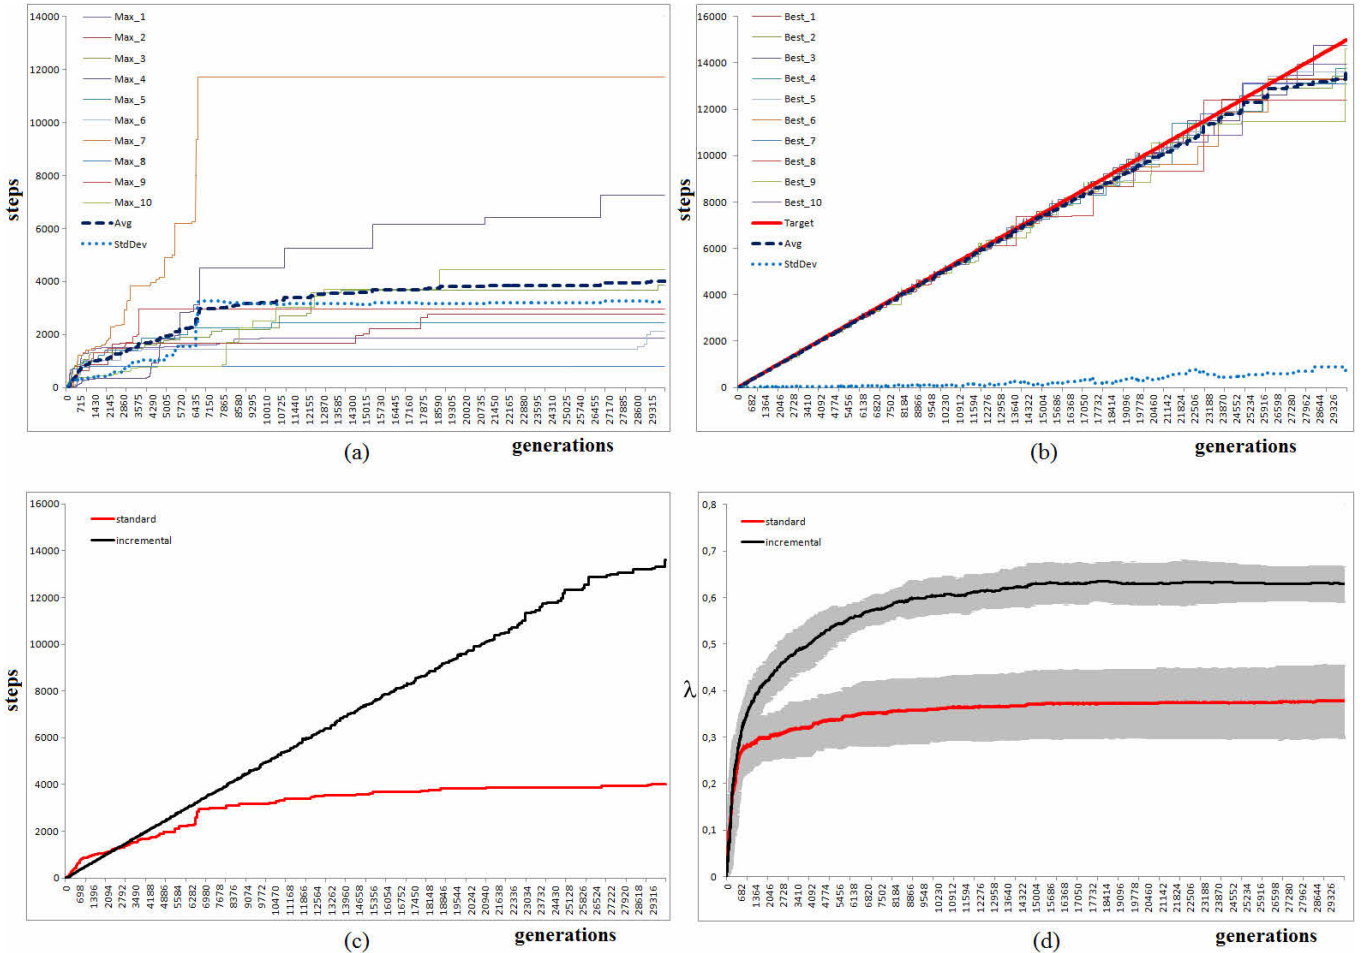

The first set of experiments consists in comparing the behavior of standard GA and incremental GA, starting from dead genomes. In both cases, the GAs run for 30000 generations. The standard approach targets the maximum attractor length for all the 30000 generations whether the incremental approach increments the target attractor length by 10 development steps every 20 generations. It is noticeable that there are clear advantages with an incremental approach for the evolution of complexity.

In Figure 4 (a) the results of a canonical GA are presented. Here the target was the maximum complexity. It is clear that a standard approach could discover in some early generations

good candidates but often the algorithm gets trapped in some unfruitful regions of the search space and for several generations there are no improvements. All the single samples are represented by the thin lines. The dashed line is the average over all the tests and after 30000 generations the attractor length has a value around 4000 development steps. Here the deviation is quite big, since in some cases the maximum length is far from the average. For example, in one case it is close to 12000 development steps while in many other cases is lower than 2000. In Figure 4 (b) the results for the incremental approach are plotted. The straight line represents the target complexity value for each generation, measured as number of development steps inside the attractor. The thin lines here follow quite accurately the target line. The dashed line represents again the average. It is possible to see that average and target are overlapping for the first 15000 generations, whether in the last 15000 generations the average is slightly lower than the target. Overall, the average attractor length after 30000 generations is around 13000 development steps. Here the deviation, represented by the dotted line, is quite small. This means that the incremental approach is able to minimize the distance from the target in each generation. Figure 4 (c) is a comparison of the two different strategies.

It is evident that the incremental approach overcomes the standard approach since the first 2500 generations. After that, the canonical GA struggles to find good solutions on average and has difficulties to evolve and jump up in complexity. On the other hand, the incremental approach shows very promising results even if in the last generations there is a small degradation of the performances. Overall, the difference between the averages is significant ( $p < .0001$ , Student's t-test).

Finally, Figure 4 (d) represents a comparison of the measured Lambda parameter in each generation. The standard GA evolves to genotypes with a maximum parameter value of 0.4. The incremental GA discovers genotypes with Lambda between 0.6 and 0.7. This means that those genotypes are in a completely different behavioral regime. Earlier work from Langton [16] identified a critical value of Lambda where the behavioral regime of the system encounters a phase transition between ordered and chaotic dynamics. In such area of the search space it is more likely to find the primitive functions to support computation: transmission, storage and modification of information. Further support to this hypothesis is given by previous work on the investigation of probable relationship between attractor length and Lambda [10]. In the experiments herein,  $\lambda$  is used as a measurement and its increase is not a

**Fig. 4:** Results for Experiment 1, developmental tables initialized with “dead genomes”. Avg. and std. dev. over 10 runs. (a) standard GA approach: generations vs. attractor length (thin lines represent single runs); (b) incremental GA approach: generations vs. attractor length (thin lines represent single runs); (c) comparison of averages: standard GA approach vs. incremental GA approach; (d) comparison of Lambda parameter:  $\lambda$  for standard GA approach vs.  $\lambda$  for incremental GA approach.

goal in itself. Figure 5 shows a plot over the  $\lambda$  space where genotypes were generated according to a specific parameter value and the resulting attractor length was measured.

**Fig. 5:** attractor length as function of  $\lambda$ . Results for 4x4 organisms and 1000 tests for each  $\lambda$  value. Adapted from [10].

In those experiments, the cellular automata configuration was the same as in the experiments herein: 2-dimensional grid with neighborhood of size 5 and 3 possible cell types. With such configuration, the most heterogeneous genotypes are generated when  $\lambda$  is 0.66. In fact, in the scattered plot, it is more likely to find long attractors in that area of the solution space. On the other hand, when  $\lambda$  is around 0.4, the behavioral regime is in an intermediate region where organisms show ordered dynamics. As such, it may be more challenging to evolve towards longer attractor lengths. Relating this results with those in Figure 4 (d), it is possible to conclude that the standard GA gets trapped in an area of the search space where the sought behavior (maximum complexity) is less likely to be found. Moreover, it may be difficult for the GA to escape from such region of the search space. The incremental approach is able to evolve genotypes with parameter value around 0.65, which may be beneficial to find longer attractors. Even if not so good solutions are found in that area of the search space, it may be still more probable for the GA to be able to discover better solutions, since the sought behavior is more likely to appear.

## Extended Evolutionary Time

Subsequently, the incremental GA is executed again for 500.000 generations and the target is incremented by 10 development steps every 500 generations. This is done to check the behavior of the GA when the algorithm has more generations to evolve and adapt the population towards the new complexity value.

In Figure 6 (a) the target line and the actual line (average) are completely overlapping. This means that, given enough time to the population to evolve to the sought complexity level, it is possible to keep increase the complexity with minimum deviation from the target. In each generation interval, the genetic algorithm is able to discover favorable genes and use it as a starting point for the next intervals. Evolution is based on already present capabilities, developed incrementally.

Figure 6 (b) and Figure 6 (c) respectively represent the average distance from the target and the percent average distance from the target. It is possible to observe that such span predictably increases along the 500000 generations. Even that, the average distance from the target level suddenly decreases below 1% since the first generations. In conclusion, it may be possible to tune the generation intervals in a way that evolution has enough time to evolve the whole population and prepare it to the following complexity improvements.

## Experiment 2: Randomized Genomes

In the second set of experiments, the behavior of standard GA and incremental GA is tested again for 50000 generations, starting from random genomes, i.e. genomes initialized with a uniform random distribution among the three cell types. By doing that, the standard GA proceeds to select the individual in the population with longest attractor length, targeting maximum complexity. As such, in Figure 7 (a) the average attractor length does not start from the origin. During the first few generations there are several jumps in complexity but after this fruitful stage the average line stabilizes and tends to become flat. Figure 7 (b) summarizes the results for the incremental approach. In this case, since complexity is evolved gradually, individuals with long attractor lengths are left aside in favor of individuals that are closer to the sought initial behavior, i.e. point attractor.

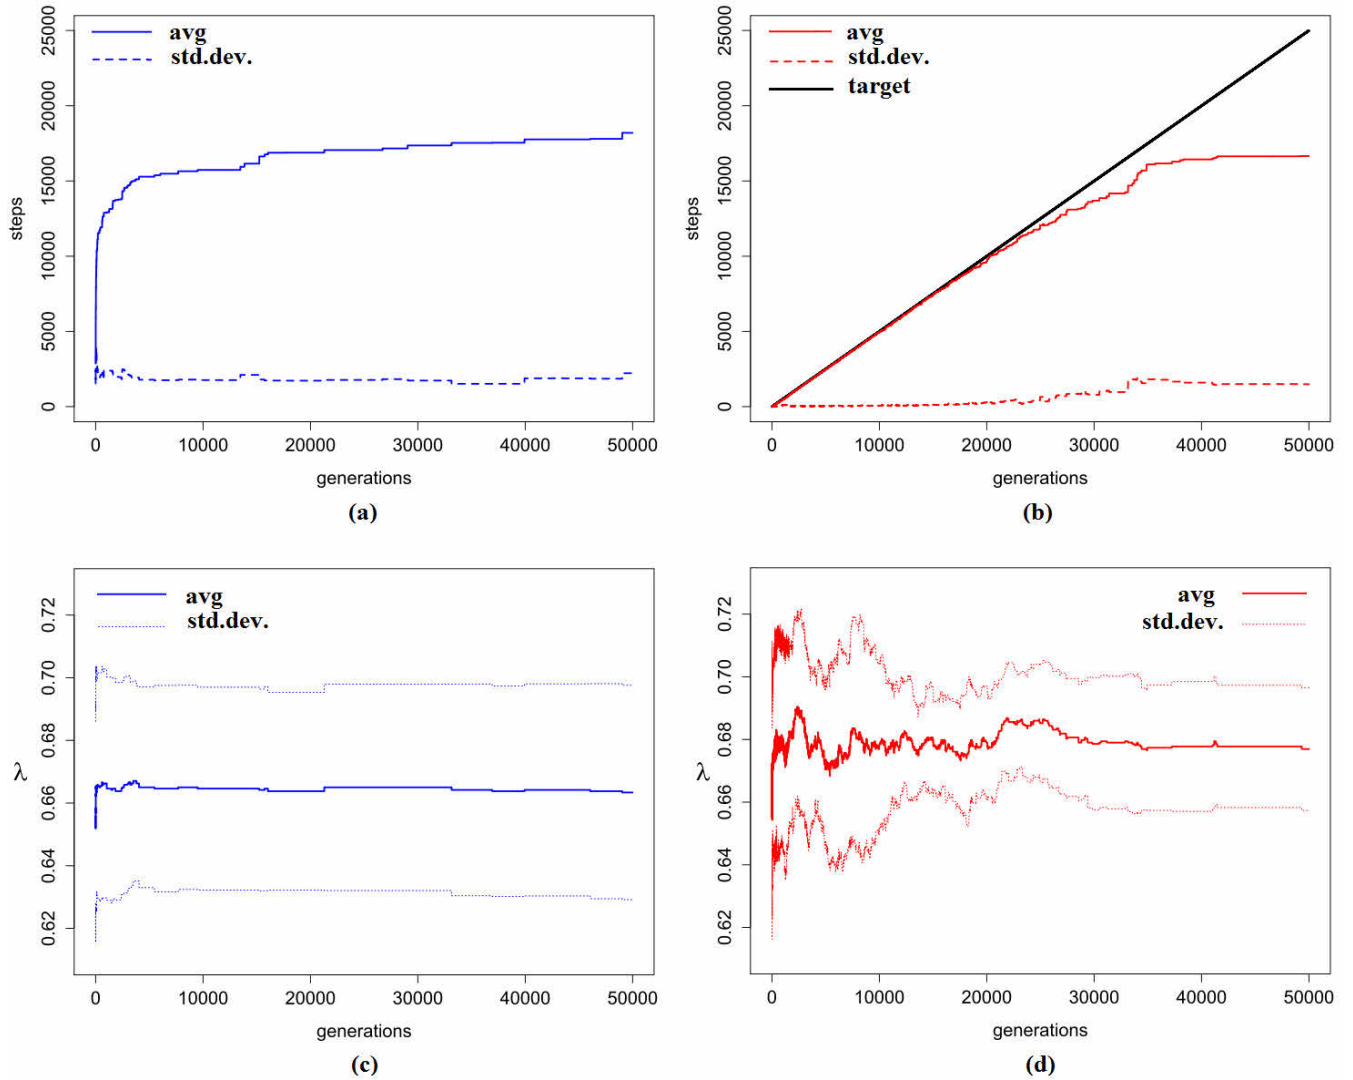

**Fig. 6:** Incremental GA approach with extended evolutionary time (500000 generations), developmental tables initialized with “dead genomes”, average over 6 runs. (a) Target attractor length and actual attractor length (overlapping); (b) Average distance from target in development steps; (c) Average distance from target %

Implicitly, in the beginning the algorithm is forcing organisms to exhibit low complexity to survive, since only in the subsequent generations the environment will become more demanding and will require evolving in complexity. During the first 25000 generations the target line and the actual line are very close. In the last 25000 generations the reached complexity level is very similar to the GA with standard fitness, both in terms of average attractor length and standard deviation. The difference between the averages is not significant ( $p=.0850$ , Student's t-test).

Figure 7 (c) and 7 (d) show the average  $\lambda$  along the generations. Since genotypes were initialized randomly, it is more likely that the developmental tables are the most heterogeneous [16].

As a result,  $\lambda$  is positioned already in an area of the solution space where highly complex individual are likely to appear. For the standard GA, the average  $\lambda$  is smoother and does not show high activity of the GA. Once the algorithm finds good solutions, it is more probable that will hardly improve with better solutions. This could be a drawback for evolvability, especially if one would like to evolve intermediate complexity levels. On the other hand, for the incremental approach,  $\lambda$  fluctuates more within the behavioral region, exhibiting high activity of the GA that continues to explore the solution space. Moreover, the incremental strategy would fit better if the system would need to reach intermediate complexity levels.

**Fig. 7:** Results for Experiment 2, developmental tables initialized with random genomes. Average and standard deviation over 10 runs. (a) standard GA approach: generations vs. attractor length (avg. and dev.); (b) incremental GA approach: generations vs. attractor length (avg. and dev.); (c) Lambda parameter for standard GA approach (avg. and dev.); (d) Lambda parameter for incremental GA approach (avg. and dev.).

## Conclusion

The presented experiments investigated the emergence of complexity in cellular machines, using two different evolutionary strategies: a standard approach, where the target was the maximum complexity and an incremental approach, where complexity was gradually evolved.

We showed that the incremental approach has clear advantages when evolution targets an increase of complexity, especially when the population's genome parameter is towards uniform, i.e. intermediate complexity levels in equilibrium with the environmental pressure. Such knowledge is important at the design stage of EvoDevo systems, where developmental actions are not manually programmed but discovered through evolutionary processes.

We also proposed the usage of Lambda genome parameter to detect the behavioral regime. This may be useful to indicate if the evolving genomes are likely to be able to achieve more complex behaviors, giving information on the evolvability of the system. Such ability of adaptive evolution is necessary for a system to be able to evolve complexity.

Moreover, when it comes to adaptivity, the results herein show that genomes with a given parameter value will most likely mutate to genomes with similar developmental behavior, as long as the mutation results in an offspring with similar parameter value. Our current work is focused on the usage of genome parameters to guide evolution towards favorable areas of the solution space. Furthermore, genome parameters may help to keep the population closer to the desired developmental behavior and supervising its genetic distance. This is in tune with at least two points of the current challenges in the field of artificial life [4]: "explain how rules and symbols are generated from physical dynamics" and "develop a theory of information processing, information flow and information generation for evolving systems".

As a future work, it may be possible to compare the robustness of solutions evolved incrementally versus solutions evolved with a standard approach. In particular, how fragile they are to external perturbation, both at genotype level, i.e. mutations in the rule table, and at phenotype level, i.e. perturbation of the system state during development.

# The ALife Zoo: cross-browser, platform-agnostic hosting of Artificial Life simulations

Simon Hickinbotham, Michael Weeks and James Austin

University of York, Computer Science Department, York, UK  
simon.hickinbotham@york.ac.uk

## Abstract

We describe a new approach to sharing software simulations that is of great potential benefit to Artificial Life researchers. youShare is an online collaborative facility that allows users to upload data, and software in the form of services. An attached execution environment allows services to be run over a heterogeneous cluster of compute nodes, where the service infrastructure guarantees that the service will be executed in the correct environment, and provide consistent results. It allows software to be made available as a service regardless of the operating system they run upon. This allows software to be maintained more easily, and to be available to all researchers with internet access. We demonstrate this by making three Artificial Life simulations available over the web: Tierra, Avida and Stringmol. These services form the foundation of an ALife “Zoo”, in which visitors can interact with ALife simulations for research and education. In addition, youShare offers a workflow facility whereby multiple services can be connected to create more complex tasks. We demonstrate the utility of this system in Artificial Life research via a workflow which calculates evolutionary activity for runs of Tierra and Stringmol.

## Introduction

It is common practice for researchers and scientists that develop their own algorithms and programs, to make them available to other researchers as source code and/or binaries. Often these are distributed to the community via personal, community or commercial websites. With a limited range of operating system (OS) configurations available to the originators of the software, it is very common that third-party developers who attempt to compile and execute these applications experience compile-time errors, dependency errors and run-time errors.

One solution is to develop and maintain source code or binaries that run on a range of operating systems. There are several problems with this approach:

- it is time consuming for the developer, who is often only experienced in writing software for personal use whilst pursuing their own research;
- considerable expertise is required to compile binaries or

install software, particularly when it has not been written by an expert in writing production-quality software;

- the code base becomes increasingly unwieldy, making development by the original authors or the community more difficult.

It should also be noted that if researchers do not make their code available, it can promote the independent development of code bases that may not conform to the original algorithm specification. The lack of availability of source code, or difficulties in compiling code if it is available, have the potential to reduce the impact of the research. The onus is therefore upon the researcher to make software available, which places further burden on a finite resource, namely the researcher’s time.

Researchers in Artificial Life (ALife) will be particularly familiar with these issues, not least due to the interdisciplinary nature of the field. A cross-disciplinary research team will have fewer skilled programmers than a pure computer science project, and fewer domain experts than a pure biological project. There are myriad ALife computer simulations available (for a list, see [http://en.wikipedia.org/wiki/Artificial\\_life#Notable\\_simulators](http://en.wikipedia.org/wiki/Artificial_life#Notable_simulators)), many of which share common themes and research applications. However, research that explores ALife issues using more than one of these simulators is rare.

In this contribution, we demonstrate a system that is capable of overcoming these issues, based upon the YouShare Virtual Laboratory (<https://portal.youshare.ac.uk>)(Austin et al., 2011). YouShare is an online collaborative facility that allows users to upload data, and software in the form of services. An attached execution environment allows services to be run over a heterogeneous cluster of compute nodes, where the service infrastructure guarantees that the service will be executed in the correct environment, and provide consistent results. Of particular interest to the ALife community may be the workflow facility that allows multiple services to be connected together to create more complex scenarios. To demonstrate this we

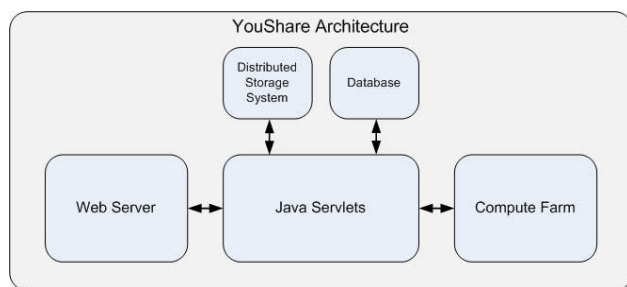

Figure 1: Overview of the YouShare Platform Architecture

have wrapped instances of a small set of representative simulators and made them publicly accessible to all YouShare users. In addition, we have created two auxiliary data analysis services that can be used on comma-delimited data files that are easily produced from the simulators.

### YouShare Platform

YouShare is an internet-based Virtual Laboratory Environment (VLE) that provides a collaborative repository for data, executable software services and workflows. The YouShare platform is based upon work achieved on the CARMEN Neuroscience platform (<http://www.carmen.org.uk>) (Watson et al., 2007) to provide a VLE for neuroscientists. YouShare extends CARMEN to be a generic, cross-domain platform for UK academics and researchers.

The YouShare platform is based upon a standard three-tier web architecture (Eckerson, 1995), as shown in figure 1. The first-tier, also known as the presentation layer, consists of a web portal, providing the user with access to the system via a web browser. The portal is built using the Google Web Toolkit (GWT), which accommodates inconsistencies in the implementations of Javascript between all the web browsers in common use today. The application layer (tier 2) consists of a group of Java Servlets, as defined by Oracle (Oracle, 2013). These provide an API onto the Data Storage Tier, and provide access to the compute servers, which are typically 8-core zeon virtual machines with 16GB RAM. The data storage layer (tier 3) comprises an SQL type database and a storage system. The database contains user accounts, metadata, system states, and the relationships between users and artefacts (files, services, metadata, workflows, etc). The storage system is used to store user's files, service implementations, and workflows.

YouShare is accessed via the portal (<https://portal.youshare.ac.uk>); a login facility provides secure access for users. Data can be uploaded to the YouShare platform, along with fully descriptive metadata (Jessop et al., 2010). Once uploaded, sharing permissions can be applied to both the data and the metadata. Several levels of sharing rights are available: private to the user; shared with specific people or groups of people; or public to

all registered users of YouShare.

Software applications can be deployed to the platform in the form of executable services. These services can be used to analyse private, shared or public data from the data repository. A service consists of the software implementation and a metadata description of the service. The services are executed on a heterogeneous array of compute servers attached to the YouShare platform. Services can be executed from the YouShare portal individually, or combined into a workflow to create more complex processing scenarios. The owners of YouShare services and workflows can set sharing permissions in a similar way to data. To aid discovery of suitable data, services and workflow, an Apache Lucene based search engine is provided to search each of the repositories.

### YouShare Services

A YouShare Service (Weeks et al. (2013)) is a combination of software that can be executed on the YouShare platform, and a metadata document to describe its operation and implementation. The software can be based upon a users proprietary code, or a common software package these can be converted into a service via a wrapping process using the YouShare Service Builder application, then deployed on the YouShare platform. We can currently create services from programs written in Python, Java, R, C/C++, Matlab, Perl, Bash/Bat scripts, or indeed most executables or scripts that can be run via a command line. YouShare Services also support multiple OS platforms, such as Linux and Windows.

The Service metadata document is a key component in the service. It provides the name and description of the service so that user's can select suitable services for their requirements. A description of the input parameters provides an interface on the portal when a service execution request is made. This interface provides a description for each input, and a suitable means to set the inputs, i.e. file browser, text box, or drop-down menu. Platform and environment specific information for the service execution can be set, to ensure that service is deployed onto the correct type of compute server, along with any data that needs to be staged. This ensures correct execution, and completely removes the need for user's to know the implementation details. Upon successful execution of the service, the metadata is used to stage the results back into the data repository and to provide a portal interface to display the output results.

### Creating Services

One of the principles behind YouShare is that users can create their own services. To this end, the service creation process needs to be quick and easy to achieve. We also need to support multiple operating systems and application programming types, and need a common method for passing data into and out of the software. These requirements can be achieved by converting the software into a command line application. Input parameters are passed into the application

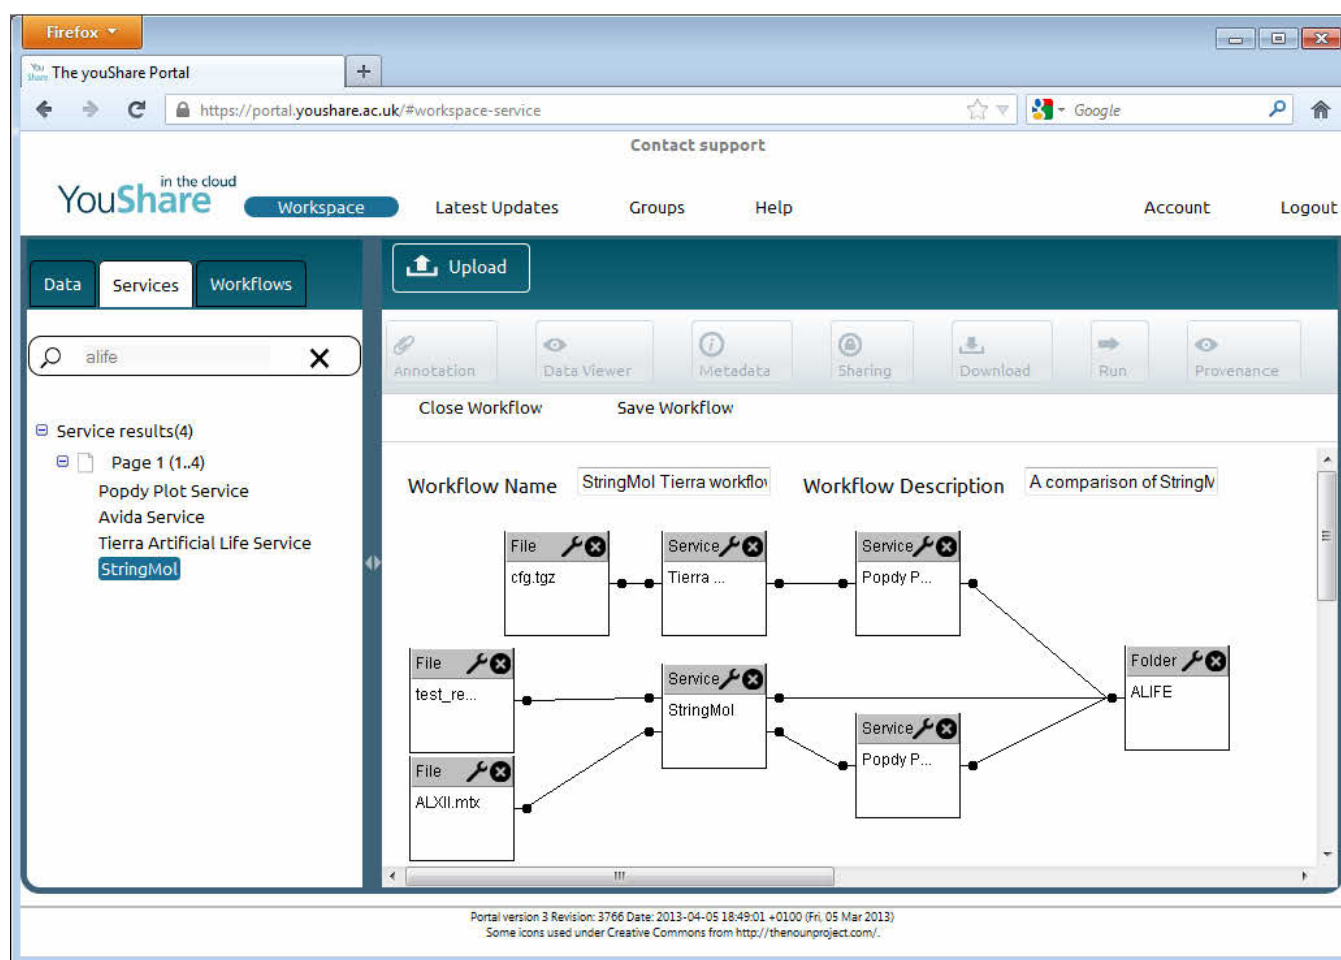

Figure 2: Example YouShare workflow consisting of Stringmol and (a modified) Tierra services being analysed by the Stringmol popdy plotting service. The results from both services are placed in the same output folder

via the command line parameter list. On completion of the application, the service needs to register its outputs in the database. This is achieved by getting the application to print any output values and/or file names to the screen (stdout) in a comma-separated list, surrounded by xml `<output>` tags, which can be achieved either by simple changes to the source code of the application, or by calling the application from a script which prints the output data once the application has finished.

To enable the command-line application to be interfaced with YouShare's Java Servlets (application layer), the application is encapsulated within a small Java class wrapper. A metadata document is also necessary to describe the application/service from a user and system standpoint. We have developed a tool, called the YouShare Service Builder, to automatically generate the wrapping and metadata. The Service Builder is a Java standalone application which uses a wizard-based approach using simple forms. The Service Builder generates a jar (Java archive) file containing the ser-

vice implementation, and an XML file containing the meta-data document. These files are uploaded to an admin panel on the portal in order to deploy the service.

## Running Services

To run a service, the user must first discover it. A search facility allows users to search the service repository, and displays a list of matching services that are accessible to that user depending on the service sharing settings. The user can browse the list of returned services and select one that is suitable. The service description can be viewed, and the service bookmarked for later use, or executed by selecting the "run" button which displays the service execution panel. This panel displays the input parameters to the service as described by the service metadata, and allows the user to select suitable data inputs. Once the inputs are set, the user can select a folder in their data repository for the results to be placed, and the service execution is then initiated. Whilst running the service execution progress is displayed

in the service log, where, upon completion the results are displayed. The results can also be viewed by browsing the specified results folder in the data repository.

## Workflows

Services can also be executed within the YouShare workflow facility that is available on the portal. Workflows allow more complex analyses to be performed, using a collection of suitable services, connected together in serial and/or parallel. The YouShare workflow tool is based on two components; a graphical workflow editor embedded into the portal, and a workflow enactment engine in the application layer servlets. The workflow editor allows users to place and connect input files, services, and output folders on the workflow editor panel. Once created a workflow can be saved and reloaded for later use. Modifying a workflow creates a newer version, though previous versions can be reloaded very simply. A workflow can be shared with other users, or groups, in the same way as files and services, however each component of the workflow must have a suitable sharing permission for a user to use a shared workflow. An example YouShare workflow is shown in figure 2. Once a workflow is ready for execution, it must be saved and the workflow editor closed. Selecting the "run" button, passes the workflow script to the workflow enactment engine. The enactment engine builds a model of the workflow, and orchestrates the service execution, and the flow of data between the service processes. Since a service implementation details are handled via the service API via the service metadata, the workflow can be constructed from a combination of services that each require different platforms and environments.

## The ALife Zoo

Having described the youShare system, we now turn to its utilisation in ALife. Our principle aim is to create an ALife "Zoo" consisting of simulators and associated data that are available to run on a single, free resource, and to foster the development of common methods of analysis of their outputs. The first step towards this goal is to make simulators available as services. In this section, we detail how this has been achieved for Tierra, Avida and Stringmol.

### Tierra as a service

The first paper on Tierra appeared in 1991 (Ray, 1991) - Tierra is close to a quarter of a century old, yet it remains highly influential. The first paper has 931 citations on google scholar. Research on Tierra is still active (Shao and Ray, 2010). Anecdotal, during the panel discussion at ECAL 2011, one of the topics was 'most influential work' - the panel unanimously credited Tierra.

**Building the core service** We downloaded Tierra version 6.02, with the patch from Matthias Rav (<http://tierra.lolwh.at/>), and compiled it on one of our CentOS5 64-bit

Linux compute servers. Rather than modify the C source code to suit our requirements, we created a bash script to wrap the Tierra command line application and provide the XML <output> tags. This ensures that the service runs as the authors of the original software intended.

One of the limitations of our service framework is that a service must have a fixed number of inputs and outputs. This can be a problem where the software that the service is built from can be configured with varying numbers of arguments. Tierra takes a group of configuration files as it's input data, and produces a number of files in an output folder. To solve this, the bash script takes in a single zip or tgz archive of input configuration files, and un-archives them to the working folder on the execution server. Similarly, the output folder is archived by the bash script to produce a single output tgz file.

When Tierra fails it does so in an interactive way, asking the user for input. As this will be executing on a remote server, Tierra would not get a user response and so the service would hang, eventually timing out. Ideally, we want the Tierra service to terminate on error, so we modified the Tierra source code by commenting out the interactive code. To provide additional robustness, the bash script performs some degree of pre-checking to see if the configuration files are complete. The Tierra command line and it's calling bash script were then wrapped using the Service Builder tool, and the resulting service was deployed on YouShare with public sharing access.

### Avida as a service

Unlike Tierra, Avida (Adami and Brown, 1994; Fortuna et al., 2013) assigns every digital organism its own protected region of memory, and executes it with a separate virtual CPU. By default, other digital organisms cannot access this memory space, neither for reading nor for writing, and cannot execute code that is not in their own memory space. A second major difference is that the virtual CPUs of different organisms can run at different speeds, such that one organism executes, for example, twice as many instructions in the same time interval as another organism. The speed at which a virtual CPU runs is determined by a number of factors, but most importantly, by the tasks that the organism performs: logical computations that the organisms can carry out to reap extra CPU speed as bonus.

**Building the Avida service** Avida is very similar in operation to Tierra, in that there are multiple input configuration files and multiple output files. The Avida C++ source code was compiled for our CentOS5 Linux environment, and a similar bash script was used to encapsulate the Avida command line executable. This script is used to pass the configuration files into the service as a single input archive file, and the output files as a single archive file. The bash script also performed some degree of checking for correctness on

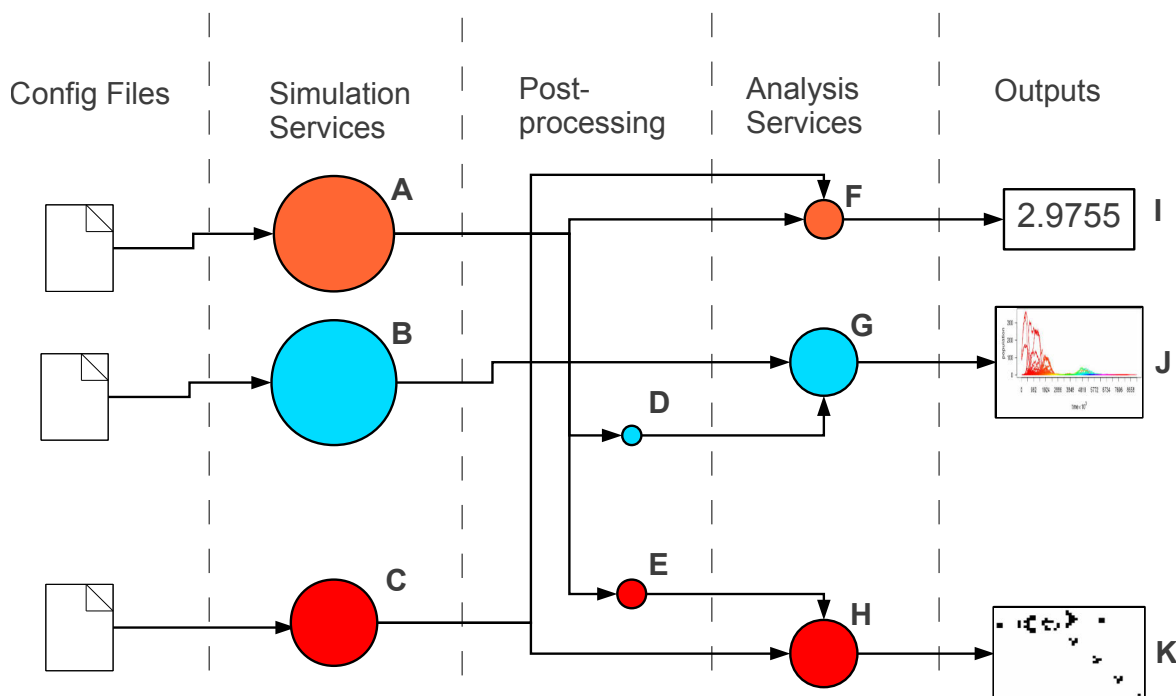

Figure 3: Hypothetical illustration of the set of possible workflows using services developed by three research groups, shown in Orange, Blue and Red. Each service is represented by a circle. The size of the circle indicates the effort involved to develop the original software (effort to wrap the software into a service is negligible). An individual workflow is constructed by connecting services together following arrows from left to right. Services developed by different teams can be linked together provided they are compatible. For example, service A can only be linked to service G if it is passed through post processing service D.

the input configuration files. We wrapped the bash script and Avida version 2.12.4 (Anon., 2012a) into a service and deployed them on YouShare with public sharing rights.

### Stringmol as a service

Stringmol is a more recent simulator which uses a much simpler model of the individual (Hickinbotham et al., 2010, 2012b). In Stringmol, there is no virtual CPU and all operations are carried out on the sequence of the individual, rather than storing values in a stack. Despite the simplicity of the implementation, Stringmol is capable of generating suprisingly innovative programs.

**Service implementation** Stingmol has not had the extensive software development that Tierra and Avida have undergone and so was much more straightforward to implement. Stringmol is written in the C++ programming language, and we compiled version 0.2.1 for our CentOS5 Linux servers, and wrapped it as a service. Two input files must be specified, plus a numerical selection of the type of simulation that is to be executed (bi-molecular interaction, simulation of a single container of molecules, or simulation of a population

of containers of molecules). However, the number of output files that are created depends on the configuration of the simulation. A script was used to collect these output files into a single zipped file that forms the output of the service.

### Analysis services

Although the three simulators described above run as stand-alone programs, each of them have auxiliary programs that are used to analyse the outputs of the simulation in order to carry out research on their behaviour. The analysis program need not be written in the same programming language as the simulator, nor need it run on the same operating system.

To illustrate how these analyses can be coupled to simulators in a workflow, we have deployed two analysis services, written in the R language. These services were originally written to analyse the outputs of the Stringmol simulator, but we have adapted Tierra to produce output that can also be analysed by these services. This approach allows analysis tools to be developed which can be used to evaluate and compare the different simulators. The first analysis service produces graphs of population dynamics of different species

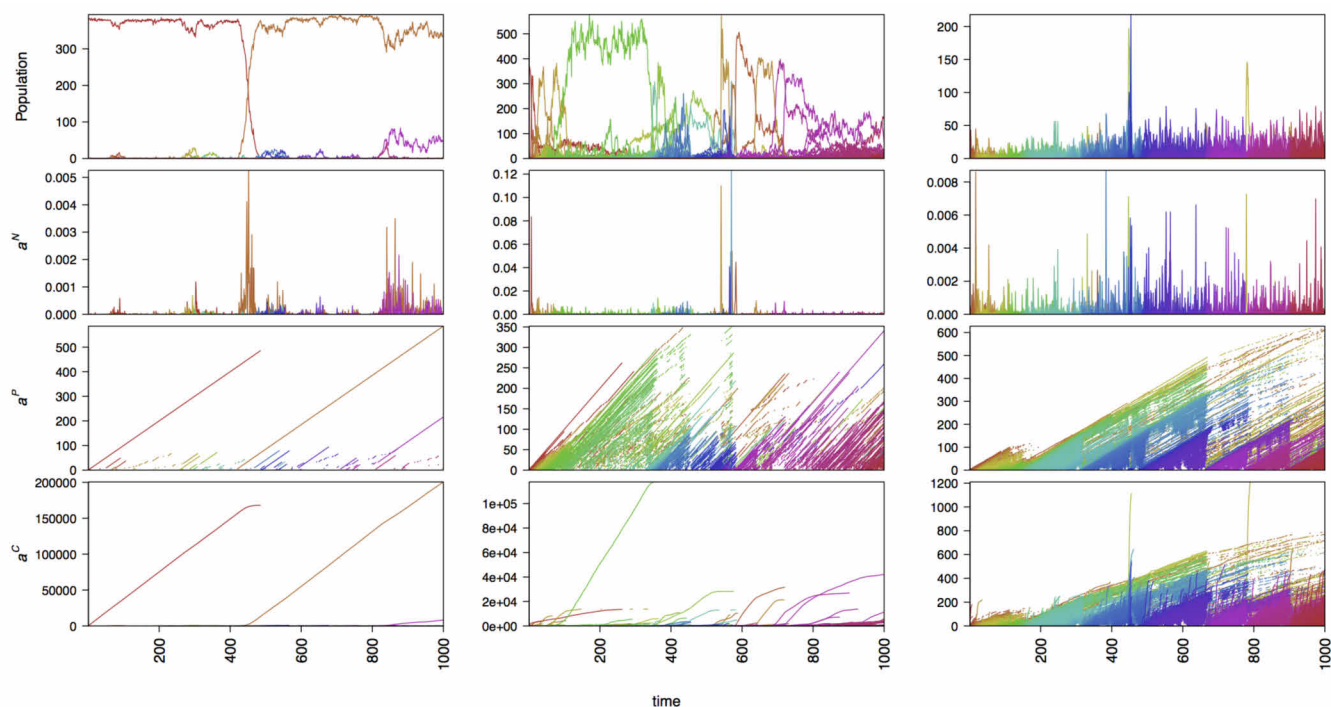

Figure 4: A plot of population dynamics (top) and non-neutral, population- and count-based measures of evolutionary activity, as executed in the workflow in figure 2. See Droop and Hickinbotham (2012) for further details

in the simulator, and the second produces a measure of evolutionary activity (Droop and Hickinbotham, 2012).

### ALife Workflows

Although the provision of software services is a useful aim in itself, the real power of the YouShare system arises when services can be connected together to form workflows. This allows research groups to collaborate on developing common research themes with relatively little effort. Figure 3 illustrates a hypothetical example of a set of workflows that use services originating from three different research teams, shown in different colours in the figure. Each team has developed an ALife simulation and an analysis tool, that have been deployed on the portal. In this example, the analyses take three forms: Numeric data (I), Graphs (J) and animations (K), demonstrating that workflows offer a powerful and efficient way of re-using code, providing a common analysis base between research groups.

#### Example - Analysis of StringMol and Tierra data

As an illustration of the workflow capabilities, we created a scenario comparing evolutionary activity in StringMol and Tierra (see figure 2). The resulting workflow automates the experiment published in Droop and Hickinbotham (2012), in which population dynamics and three measures of evolutionary activity we calculated for configurations of Tierra and StringMol, configured with a range of mutation rates.

To achieve this, we created a modified Tierra service so that it created output in StringMol format. The "popdy plotting service" was then created, based on existing R code that produced visualisation of the StringMol output data. The workflow loads data from a publicly shared location, pushes the data into both StringMol and Tierra, the outputs of which are separately analysed and written to a directory in the current user space.

Upon completion of the workflow execution, the output folder contains two PDF files from the Tierra and StringMol analyses respectively. See figure 4 for the analysis of Tierra data. The top row shows the population dynamics of different component types in Tierra during the run. The second row shows the non-neutral evolutionary activity, and the third and fourth rows show population- and count- based evolutionary activities of Bedau et al. (1997).

The output folder also contains an optional log file that was generated by the StringMol service. This workflow has been shared publicly for all users of YouShare.

### Further Work

For the current contribution, we have implemented the ALife Zoo in the generic YouShare system. This allows a test of concept to be created quickly, and range of other generic services that have been implemented for other research domains to be available. Like many web applications, YouShare undergoes constant improvements as the user and

code base expands. Whilst the ALife Zoo could be hosted by the “vanilla plain” YouShare platform on an ongoing basis, we recognise that there may be special demands for specific features from the ALife research community. It is possible to branch the first tier of the service to deliver a bespoke user experience. We have successfully done this for several projects (e.g. Hickinbotham et al. (2012a)). Below we discuss potential improvements to the core YouShare system that could be implemented in future.

### Visualisation

Where simulations produce large amounts of output data, it is desirable to create a visualisation of the data before deciding to download the data and proceeding to more detailed analysis. This problem has been partially addressed in the CMAC project, where interactive visualisation of the service output is made available on-line using the Raphael Javascript library (Anon., 2012b). The challenge in ALife Zoo is to make these visualisations as informative as possible, whilst keeping them sufficiently generic to be applicable to a range of simulations.

### Linking to Publications

YouShare was developed to function as a Virtual Laboratory, and since publications are a permanent record of the work in Laboratories, it makes sense to link them to their data, services and workflows in YouShare. A facility to make such links is currently under development.

### Linking to External HPC

Although the compute resource in YouShare is considerable, it is not infinite. Certain services may require high-memory or many-core processing to be delivered in a timely manner. YouShare could be extended to carry out the interfacing and staging of jobs on HPC clusters with relative ease, and so combine the advantages of HPC with the advantages of a browser-based user interface. A key issue here is handling big data, but ALife simulations tend to be relatively small in terms of their data footprint.

### Linking to External Tier 1 Server

Finally, it is possible that particular specimens in the ALife Zoo may require special handling in their presentation to the public. In other words, the GWT-based youShare portal may not be sufficiently flexible to demonstrate particular simulations. For example, it would be extremely difficult to implement Avida-Ed, the educational version of Avida, in YouShare, due to the highly graphical and interactive nature of the interface. However, it is possible to develop other browser based front ends (for example, a LifeRay portal) that could access the YouShare back end whilst delivering a highly specialised user interface.

### Exposing services to other web applications

Since the services in youShare are RESTful, it is straightforward to make them available to other web applications, rather than using the generic portal. We are in the process of developing an API to make these services available in this way. The main issue to be addressed is the maintenance and handling of user access rights to youShare.

### Conclusion

YouShare provides a method for collaborative sharing of data and software. Software is deployed as “ready to go” services that are guaranteed to be deployed on the correct platforms of a heterogeneous compute facility. However, service implementation details are hidden from the user, allowing them to concentrate on service functionality alone. Mixed-platform services can be combined in a workflow environment to create more powerful tools. The YouShare compute facility can be extended to the Cloud, and with Virtual Machine (VM) technology we provide a sustainable software model. YouShare also encourages cross-domain research; there are currently 83 services on YouShare, including the new ALife services we describe here. These are a mix of Windows, Scientific Linux 4, and CentOS Linux 5 services, and cover domains such as neuroscience, text mining, image/3D processing, and neural networks, as well as generic services.

Two of the ALife services and workflows we report in this contribution have been highly influential in the field over the past two decades. With relatively little effort, and thanks to their open-source licenses, we have been able to make them available as web services for the first time. We are also able to show how analysis services developed more recently can be used to analyse the outputs of Tierra. This demonstrates that platforms such as YouShare are able to create flows of configuration, simulation and analysis between ALife researchers in a novel and efficient manner.

# A Temporal Pattern Predictor for Virtual Characters

<sup>1</sup>University of Brighton, UK  
m.m.rosenkind@brighton.ac.uk

## Abstract

This paper discusses a prototype of a temporal pattern predictor, which was built on specifications derived from the descriptions of the “Ergotrix” temporal memory network in Valentino Braitenberg’s “Vehicles” (Braitenberg, 1984). The prototype was developed as a component for a control architecture for virtual characters.

## Introduction

In Valentino Braitenberg’s “Vehicles - Experiments in Synthetic Psychology” (Braitenberg, 1984), the author describes a temporal pattern memory component that enables the synthetic creatures to base their behaviour on past experiences: Rather than just reacting to the currently perceived sensory stimuli, these agents first form predictions based on the statistical probability of previously perceived patterns re-occurring. These predictions then form the basis for their actions. In other words, the creature reacts to a pattern of expected stimuli, instead of waiting for the stimulus to actually occur.

Braitenberg’s temporal pattern memory component is implemented in the form of a connectionist network of nodes. In such a network, each node may represent the presence of a sensory stimulus, a pixel on a screen or a sensory ‘value’ of another kind (e.g. the distance value of an infra-red sensor). The individual nodes can potentially form connections (which are often referred to as associations) to any other nodes in the network. The strength of the connection is determined by the connection weight.

In many classical neural network models, such as feed-forward or back propagation networks, (e.g. McCulloch Pitts 1943, Bryson and Ho 1969,), the connection weights are set using sophisticated learning algorithms. However, many of these separate the process of setting weights (learning or training phase), from actually using the network (execution phase). The model presented in this paper, uses a learning model that can form new associations while it is being used. This learning rule is based on Hebb’s “what fires together, wires together” postulate (non-verbatim from Hebb, 1949), which itself tried to summarize the general behaviour of connecting neurons in biological brains.

Regardless of the learning rule used, traditional implementations of connectionist networks will see that a signal passes from active nodes to all their connected peers.

The amount of activity transmitted is determined by the weight of the connection.

In addition to the properties that define a Hebbian learning-based neural network, Braitenberg specifies two further key characteristics, which our network model intends to address:

1. The memory network associates only elements that are active in succession, within a brief delay and not those, which are active simultaneously. This differentiates it from a basic associative connectionist network.
2. Memorized patterns can be reproduced at an arbitrary speed. If they are reproduced at a more rapid pace than they are likely to occur as sensed via the sensory system, the network acts as a predictor.

These two functional requirements were at the core of a series of our incremental prototypical experiments.

## Methods

### A Fixed-Delay Network

After initial investigation into delay-line networks, which used timers to record variable activation delays between a set of elements (see Figure 1), we employed a network with fixed delays between the activation of elements. The previous models had focused on implementing the ability of modelling a variety of time delays between device pairs in order to learn temporal patterns in threshold device populations. The model discussed in this paper moves away from this variable delay paradigm towards a notion inspired by the way film cameras record the passage of time. Film cameras are usually set to operate at a fixed frame-rate; say 25 frames per second (fps). When a slowly moving object passes by the camera lens it leaves a contiguous trace of strongly activated pixels on the film (or CCD chip for that matter). On the other hand, if a fast moving object passes by the camera lens, it would only leave trace signals on a few, further apart areas of the film/CCD chip. Thus the speed of the object is represented by two distinct patterns on the film, even though the delay between the activation of the neighbouring contiguous pixels was the same in both cases. The time delay between the contiguous and distant impressions was 1/25 of a second.

This model uses the idea that speed is not a matter of delaying information transmission between devices. At one time-step the delay between one node activating another is always

constant. Rather, time is a property of an observed object and the pattern that its observation leaves in the connections of a perceiving network. Figure 1 illustrates the fixed delay network. The activation timing between each pair of devices in the network is fixed. The timings are not stored in the connections, but in the patterns that are left when sensed by a group of connected devices.

Figure 1 Illustrates variable delay and fixed delay paradigms

Applying the above example to a network of connected nodes ABCDEF, that are aligned in the visual field of a camera from left to right and an object passes by them at slow speed, then all devices A-B-C-D-E-F will be activated in sequence. If the object passes by at high speed, some visual receptors might actually fully activate- in this case only triggering the sequence A-C-E for example.

Thus, even though the activation speed between the threshold devices in the visual receptor is constant, they can capture different timings/speeds within varying received activation patterns.

Comparing this theoretical model to the subjective experience of observing moving objects, an object moving past a photo-cell faster would allow less light to pass from it into any given receptor - therefore triggering a weaker activation signal. In addition there even seems to be a threshold for the maximum speed that can be perceived by a given visual system. A very high velocity object, such as a spinning airplane propeller may appear to be entirely transparent, with only a slight "dimming" of the background signifying their presence.

To summarize: If time is a property of the object being observed and is not represented in the network as a property of the connections between nodes, then time is perceived and encoded as a pattern in the network and not as a value. This makes time a relation between an observed object's speed/rate of movement and an observer's perception/processing rate.

Based on initial observations, the predictor model had to address the following issues:

1. Feedback loops can create uncontrolled activity and irrecoverable states.
2. One time-step is not sufficient for accurate long-term predictions. A short-term, working memory should be used to extend the predictor.
3. Currently, every association is stored, leading to a quick saturation of the network. Competition and pattern decay should be introduced to:
  - a. Resolve conflict between opposing patterns
  - b. Decay old and rare patterns over time

## Results

### The Algorithm

The first version of a model based around the notion of a fixed-delay network used a very simple algorithm. At each time step, the currently firing network node is associated with the node that fired on the previous time step. The association is uni-directional, meaning that only the connection *from* the previous node is reinforced, while the connection *to* that node is not reinforced. The association weight is determined by the time that has passed since the previous node fired.

The initial implementation used a counter to determine the time that had passed between the firing of the two connected nodes. However, due to requiring counters for each node that fires during a single time step, the revised implementations instead use an extension of the action-potential charge of each node. While traditional artificial neural networks use a binary charge state of either 1 or 0, this extended model still outputs a binary energy value, but instead of returning to 0 immediately, the value is gradually decreased over a series of time steps. This made it possible to use the *charge falloff* as an individual measure of time for each node.

Below is the pseudo code for the algorithm used:

For each node **A** in the network

```
//Update CURRENT and PREDICTED charge:
•Retrieve charge from previous time step
•Decay the previous charge
•Add external stimuli to charge

•Calculate internal stimuli
  •For each node B (that is not A) that
    fired on the previous time step (in
    fired list)
    •If previous node B is connected to
      current node A
      •Calculate and add the input
        charge from B to A (node B's
        output & weight from B to A)
      •Decay the connection weight from
        A to B (if a connection exists)

  •Update current charge for node A
    (previous charge + external stimuli)
  •Update the predicted charge for node
    A (internal stimuli / past effect
    scaling value)

//Fire Nodes and Update Associations:
•If current charge > threshold
  •For each node B (that is not A) that
    fired on the previous time step
    •Increase the weight from B to A
    •Decrease the weight from A to B (if
      a connection exists)
  •Add the current node A to the fired
    list
  •Remove the oldest element from the
    fired list
```

The model showed the capability of reproducing time series patterns, albeit without any intermittent pauses between node activations. The pattern *sequence* was reproduced faithfully, but the reproduction was sped up with each node activating exactly one time-step after the previous one.

Another issue was that pattern loops could end up creating feedback patterns similar to Conway's "Game of Life" (Gardner, 1970).

### Separating Internal Activity from Prediction

The first change from the previous model was that the *predicted activity* was separated from the *actual activity* in the network. Instead of adding the internal activation energy to the total *charge* of each node (which determines whether the node would fire), it is instead accumulated in a new node property, the *prediction*. In the visualization that was used in our simulation, the *prediction* and the *charge* are displayed as two separate coloured bars to make it clear to the observer which was the *charge* caused by external stimulus and which was the predicted path. Separating the two immediately resolved the internal feedback problem of course. Figure 2 shows the implementation of the temporal pattern predictor which visualizes the separation between sensory input and prediction. The left most active threshold device is currently active. The two paths emanating from it are two previously perceived patterns of node activity. The darker shading indicates that a predicted pattern has been perceived more often and/or more recently than the weaker prediction.

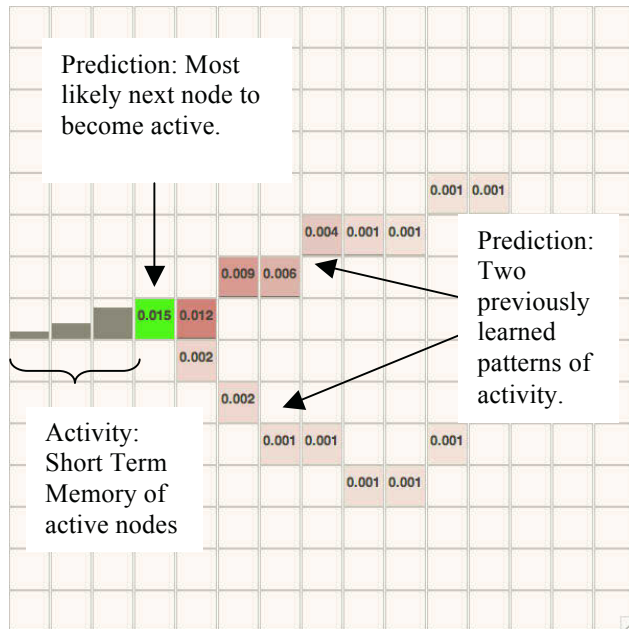

Figure 2 The Predictor model implementation

### Short Term Memory Trajectory

The main problem that occurred with the previous version of the predictor was that of pattern interference. In a network, any given node may be part of several trained patterns. When this node is activated, how does the network *choose* which

pattern to activate? While any of the patterns are valid when taking into account only the current state of the network, viewed as a series of states in *time*, the idea of all being valid becomes less likely. To illustrate this, the diagram in Figure 3 shows an experiment that sees four different opposing stimulus sequences presented to the network. Each of the four sequences passes through the same middle node and sequence pairs 1&2 and 3&4 share the same path. Figure 4 shows the false predictions the current model makes.

Figure 3 Experiment setup to test pattern interference

Figure 4 The false predictions the network makes due to pattern interference

Note how only 9 unique states can be identified from the perspective of this network. Viewing state C without taking the preceding time-steps into account, the predictor could validly predict either state D,B,H or G as the next possible position in the sequence.

In order to deal with this problem of differentiating between different temporal patterns, a short-term memory was introduced into the model. This sees a series of *past devices* associated to the current device under the notion that they are precursors of the currently active device. The further in the past these devices are active, the weaker the association to the current device. Figure 5 is an illustration of this mechanism. It shows an example of impact of short-term memory the possible predicted paths A, B and C. While all three are equally likely from the perspective of the current node, the

Figure 5 Diagram illustrating how the short-term memory allows the network to differentiate between predicted patterns.

additional stimulus from the two previous nodes in the short-term memory accumulate to support path C as the most likely pattern.

The result of adding a short-term memory of past nodes to the model is illustrated in Figure 6. The *perception* of the predictor has changed as it keeps the series of past nodes in mind. From the outset, this allows the network to differentiate between 20 unique states instead of just 9.

Figure 6 Introducing a short-term memory of active nodes changes the perception of the network

Based on the altered perception, Figure 7 shows that these 20 states are then associated with 20 different predictions. Since the influence from the short-term memory adds additional activity to the network, the problem of saturating the entire network becomes relevant. To deal with this problem the model needs to include the notion that certain patterns are *competitive* in that they represent opposing positions to a fact.

Figure 7 Using a short-term memory allows the network to differentiate between predictions

Figure 8 Pattern Inhibition enhances the prediction by inhibiting patterns only pointed to by individual nodes.

### Pattern Inhibition

A simple form of competition that was tested with this model was inhibition between patterns. Inspired by the lateral inhibition algorithm commonly used in edge-enhancement algorithms in computer vision, this mechanism allows currently active nodes and the nodes in short-term memory to inhibit all the nodes that they are currently not connected to. The result is a cumulative effect of inhibition. In parallel with exciting connected nodes as depicted in Figure 5, past and present nodes will inhibit every other node in the network, thus *enhancing* the strongest mutual patterns among them. Figure 8 illustrates this effect.

### Discussion and Further work

Since the model uses fixed delays, the predicted sequence is triggered simultaneously. Speeding up a predicted pattern is certainly desirable according to Braitenberg, who states that a predictive brain would need to “reproduce sequences at a more rapid pace” (Braitenberg, 1984, pg. 72). However, the interval information between the activation of nodes is lost, which contradicts Braitenberg’s earlier statement that “we implicitly assumed that the Ergotrix wires would be trained to reproduce sequences of activation at the same pace as the original occurrence of the sequences of events.” (Braitenberg, 1984, pg. 72).

Overcoming this issue would require re-introducing some form of internal self-activation to the network, albeit with a mechanism for preventing undesirable states such as feedback loops.

While this internal dynamic is desirable in a future model of the predictor mechanism, a feedback-free predictor has the benefit of stability and the ability to clearly visualize the discrepancy between sensed input and predicted output. It might also be possible to derive the timings from the prediction value of nodes.

### Further Work

Testing the predictor in an embedded scenario is the primary priority at this point. Two experiments are currently being prepared. The following is a summary of some of the early findings.

The scenario for both experiments is a chase-and-catch setup, with the goal being to stay as close as possible to a moving target. The simulation features a differential drive-driven agent with two distance sensors, which can be set to track a target. The aim of these experiments is to see whether adding the ability to anticipate the path of a moving target leads to more optimal behaviour. Note that in both experiments, the tracked target is moving *faster* than the agent. To catch the target, the agent therefore needs to intercept the target:

The first experiment implements the predictor as a probabilistic occupancy map (POM), inspired by previous work by Damian Isla (2002a, 2002b). The experiment sees the predictor network represent the location of a tracked object on an occupancy grid. The predictions generated therefore propose the possible future location of the tracked object and an agent’s sensors can be set to track the prediction instead of the ‘actual’ tracked object. This can be implemented using the current predictor, which only tracks a single point (the location of the object on the map).

Figure 9 shows the path of the agent without using the predicted position of the target, indicated by a cross. Figure 10 shows that the agent manages to get closer to the target when using the predicted position as the input. While this early result shows that our predictor can function as a POM, the result is still highly dependent on tuning. Further Increasing the speed of the target, would require an agent that is capable of adopting a strategy that does not involve it following the target, but instead waiting for it at an expected location. The current predictor would need to be extended to allow for such behaviour.

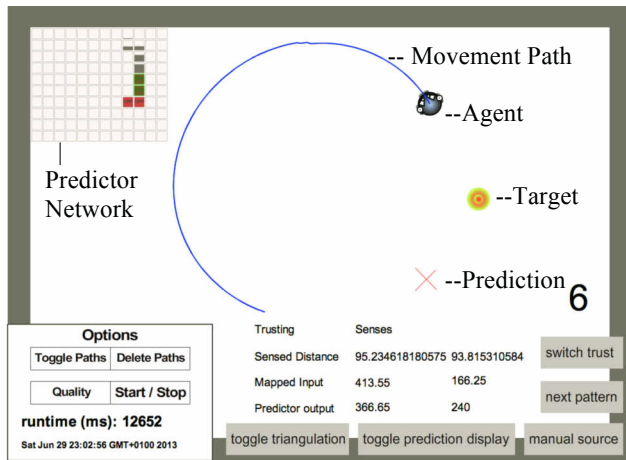

Figure 9 Chase-scenario with a moving target. The objective is to stay as close to the moving target as possible.

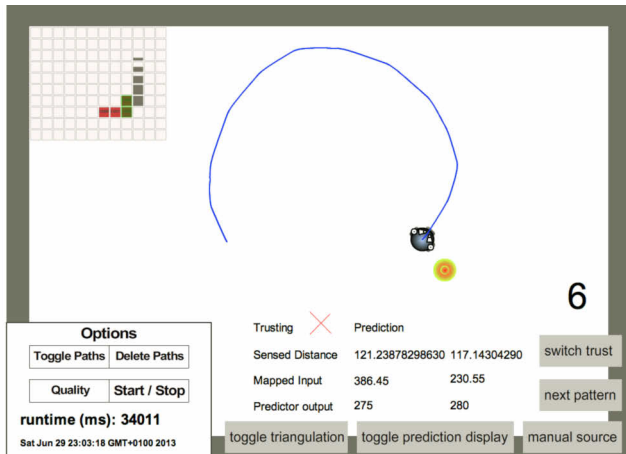

Figure 10 Using the predicted position of the target improves the behaviour.

Figure 11 shows the second experiment, which uses the predictor to generate a multi-dimensional sensory space. By using multiple individual predictors, one for each sensor input, separate predictions of the expected future state of each sensor are generated. In this case, the sensors used are two distance sensors. To function with the current predictor model, the distance reading need to be converted into discrete values that can be mapped to the predictor grid. Thus finding a suitable approach to balancing the performance and the accuracy of the predictions will be of particular interest.

The two distance sensor readings are not sufficient to accurately triangulate and predict the position of an object's position, since the distance sensors are omni-directional and always return a positive distance measurement in our simulation. The agent therefore requires an additional internal calculation that tells it in which direction (in front or behind) the observed object is. Combining this with the sensor readings thus gives discrete values ranging from negative

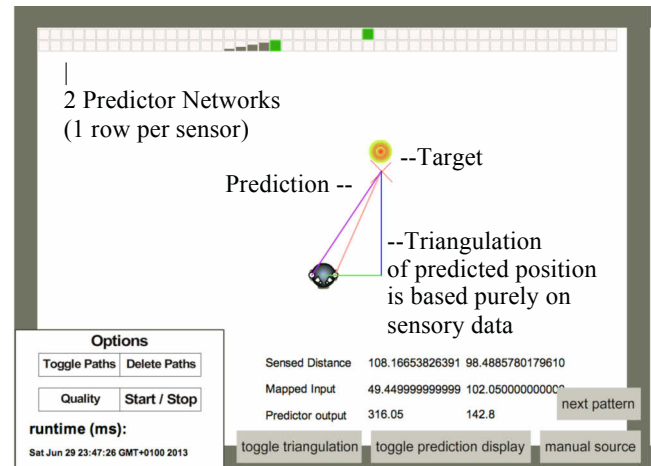

Figure 11 Experiment testing the use of the predictor network to anticipate sensory data. The future position of the target is triangulated and displayed.

(behind) to positive (in front) that can be fed into the predictor network. While this model already works for a stationary agent, the main issue that remains is effect of self-movement on the sensed values. This feedback-loop between the relative position of the agent with regard to the tracked object has to take into account, or rather counteract, the effect that self-movement has on the sensory data. Without this additional system in place, the current prototype will only work in a stationary agent, observing and predicting the location of a moving tracked object using its distance sensors.

## Conclusions

Our model of a Braitenberg-inspired temporal pattern predictor can successfully predict and visualize the path of a moving object and can avoid interference between crossing patterns through the use of short-term memory. A set of experiments successfully tested the model in the context of a chase scenario and has revealed several ways in which the current model could be further improved.

In the first experiment, the choice between following the sensed position of the target versus the predicted position on the occupancy map was controlled by the experiment. Using the user interface we were able to switch between the two and compare the resulting behaviours of the agent. A central topic for further research on our particular predictor model is the inclusion of an automatic switching mechanism that enables the agent to make a choice between purely reactive behaviour (following the sensory input directly) and pro-active behaviour (following the internal representation of the target on the POM). This in turn could be extended to include the ability to optimise the prediction mechanism by re-enforcing accurate predictions. Braitenberg's original description of the predictor includes this functionality and suggests a method of positive reinforcement based on classical conditioning (Pavlov, 1903).

The current model only supports sequences of single nodes. It only allows a single *past node* to be associate with a single

*current node*. To allow for more complex patterns and a wider range of application, it should be possible to associate groups of *past nodes* with groups of *current nodes*. The ability to support multi-point patterns could improve the predictor further. Connecting the currently separate sensor readings to the same network should give the predictor more evidence to base individual predictions on. As we saw with the inclusion of short-term memory, this could potentially improve its ability to differentiate between similar patterns.

# Evolution of Tail-Call Optimization in a Population of Self-Hosting Compilers

Lance R. Williams<sup>1</sup>

<sup>1</sup>Department of Computer Science, University of New Mexico, Albuquerque, NM 87131  
williams@cs.unm.edu

## Abstract

We demonstrate the evolution of a more complex and more efficient self-replicating computer program from a less complex and less efficient ancestor. Both programs, which employ a novel method of self-replication based on compiling their own source code, are significantly more complex than programs which reproduce by copying themselves, and which have only exhibited evolution of degenerate methods of self-replication.

## Introduction

Among living organisms, which employ many and varied mechanisms in the process of reproduction, examples of evolved mechanisms which are both more complex and more efficient than ancestral mechanisms, abound. Yet, nearly twenty years after (Ray, 1994)'s groundbreaking work on the Tierra system, in which the evolution of many novel (but degenerate) methods of self-replication was first demonstrated, there is still no example of a more complex and more efficient self-replicating computer program evolving from a less complex and less efficient ancestor.

This is not to say that there has been no progress in the field of artificial life since Tierra. Nor are we suggesting that increased reproductive efficiency is the only evolutionary path to increased complexity. The evolution of self-replicating programs of increased complexity has been demonstrated many times (Koza, 1994; Taylor and Hallam, 1997; Spector and Robinson, 2002), and perhaps most convincingly in the Avida system (Adami et al., 1994). However, more complex programs evolved in Avida only because complexity was artificially equated with efficiency in the sense that programs which learned to solve problems unrelated to self-replication were rewarded with larger rations of CPU time. No program in Avida (or in any other system known to us) has ever evolved a method of self-replication that is both more complex and more efficient than the method employed by its ancestor.

## A New Kind of Artificial Organism

Self-replicating programs have been written in both high-level languages and machine languages. We define a ma-

chine language program to be *interesting* if it prints a string at least as long as itself and halts when executed, and observe that the Kolmogorov complexity of interesting programs is lower than that of random strings of similar length. Now, if we were to train an adaptive compression algorithm on a large set of interesting programs, then the compressed programs which result would *look* like random strings. However, by virtue of being shorter, they would be more numerous relative to truly random strings of similar length. It follows that compression, which *decreases* redundancy by replacing recurring sequences of instructions with invented names, *increases* the density of interesting programs.

Since both processes increase redundancy and output machine language programs, it is natural to identify *decompression* with *compilation*, which increases redundancy by repeatedly generating similar sequences of instructions while traversing a parse tree. Viewed this way, programs written in (more expressive) high-level languages are compressed machine language programs, and compiling is the process of decompressing source code strings into object code strings which can be executed by a CPU.

If the density of interesting programs increases with the expressiveness of the language in which they are encoded (as the above strongly suggests), then one should use the most expressive language possible for any process, like genetic programming, which involves searching the space of interesting programs. However, if the goal is building artificial organisms, then high-level languages have a very serious drawback when compared to machine language. Namely, programs in high-level languages must be compiled into machine language before they can be executed by a CPU or be reified as a *distributed virtual machine* (Williams, 2012).

Given that we want our self-replicating programs to be both (potentially) reifiable and to evolve into programs of greater complexity and efficiency, we must ask: How can the advantages which derive from the use of a high-level language for genetic programming be reconciled with the fact that only machine language programs can be reified?

To address this question, we introduce a new and significantly more complex kind of artificial organism—a ma-

Figure 1: Conventional self-replicating program (left) copies itself by exploiting program-data equivalence of von Neumann architecture. Compiling quine self-replicating program (right) with source code genotype (green) and object code phenotype (red). Because the shortest correct implementation of copy is optimal, only the compiling quine is capable of non-degenerate evolution.

chine language program which reproduces by compiling its own source-code. See Figure 1. Conventional self-replicating programs reproduce by copying themselves. Optimum copiers accomplish this in time proportional to their length, and it is not very hard to write a copier which is optimum in this sense (or for one to evolve). It follows that shorter implementations are always more efficient, which leads to degenerate evolution, absent factors beyond efficiency. The possible variation in the implementation of a compiler is far larger. Even if the definition of the object language is stipulated, there is still a huge space of alternative implementations, including the syntax and semantics of the source language, the ordering of the decision tree performing syntactic analysis, and the presence (or absence) and effectiveness of any object code optimizing procedures.

In this paper we describe a machine language program which reproduces by compiling its own source code and use genetic programming to demonstrate its capacity for non-degenerate evolution. In the process we address questions such as: How can a program like a compiler, which implements a complex prescribed transformation, evolve improvements while avoiding non-functional intermediate forms? How can two lexically scoped programs be combined by crossover without breaking the product? How can a more efficient self-replicating program evolve from a less efficient ancestor when all mutations initially yield higher self-replication cost?

### A Simple Programming Language

Because a self-hosting compiler compiles the same language it is written in, it can compile itself. The language we used to construct our self-hosting compiler is a pure functional subset of Scheme which we call *Skeme*. Because it is purely functional, *define*, which associates values with names in a global environment using mutation, and *letrec*, which also uses mutation, have been excluded. The global environment itself is eliminated by making primitive functions constants. For simplicity, closures are restricted to one argu-

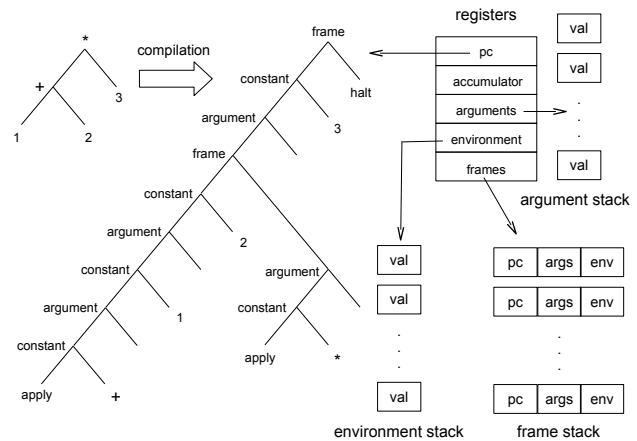

Figure 2: Virtual machine for evaluating compiled Scheme expressions showing its registers and associated heap-allocated data structures (Dybvig, 1987).

ment; user defined functions with more than one argument must be written in a curried style. This simplifies the representation of the lexical environment which is used at run-time by making all variable references integer offsets into a flat environment stack; these are termed *de Bruijn indices* and can be used instead of symbols to represent bound variables (De Bruijn, 1972).

One feature peculiar to Skeme is the special-form, *lambda+*. When a closure is created by *lambda+*, the closure's address is added to the front of the enclosed environment; the de Bruijn index for this address can then be used for recursive function calls. For example, the following function computes factorial:

```
(lambda+ (if (= %0 0) 1 (* %0 (%1 (- %0 1)))))
```

where *%0* is a reference to the closure's argument and *%1* is a reference to the closure's address.

### Tail-Call Optimization

Because the very first self-hosting compiler was written in Lisp, it is not surprising that it is possible (by including primitive functions which construct bytecode types) to write a very small self-hosting compiler in Skeme. See Figures 2 and 3.

The cost of compiling a given source code depends not only on its size, but also on the complexity of the source language, the efficiency of the compiler, and the cost of any object code optimizations it performs. Common compiler optimizations include constant folding, loop unrolling, function inlining, loop-invariant code motion, elimination of common subexpressions, and dead code elimination. Since a self-hosting compiler compiles *itself*, the efficiency of the object code it *generates* also affects compilation cost; it follows that minimizing the cost of self-compilation involves a complex set of tradeoffs. The most important of these is that object code optimizations must pay for themselves by yielding an increase in object code efficiency large enough

to offset the additional cost of compiling the source code implementing the optimization.

Most of the overhead associated with a function call involves the saving and restoration of evaluation contexts. In Skeme, these operations are performed by the *frame* and *return* bytecodes which push and pop the frame stack. However, when one function calls another function in a *tail position*, there is no need to save an evaluation context, because the restored context will just be discarded when the first function returns. A compiler which performs *tail-call optimization* recognizes when a function is called in a tail position and does not generate the code which saves and restores evaluation contexts. This not only saves time, it also saves space, since tail recursive function calls will not increase the size of the frame stack at runtime.

### A Quine which Compiles Itself

A *quine* is a program which prints itself. It is possible to write a quine in any programming language but Skeme's list-based syntax makes it possible to write especially short and simple quines. For example, in the following Skeme quine, an expression  $(\text{lambda } (\text{list } \%0 (\text{list quote } \%0)))$  which evaluates to a closure which appends a value to the same value quoted is applied to the same expression quoted:

```
((lambda (list %0 (list quote %0)))
 (quote (lambda (list %0 (list quote %0)))))
```

It is possible to define an expression  $\phi$  in Skeme which can compile any Skeme expression. The expression  $\phi$  evaluates to a curried function which takes a compiled expression and an uncompiled expression as arguments. The compiled expression is a *continuation*; the uncompiled expression is the source code to be compiled; applying the curried function to the halt bytecode yields a function which can compile top-level expressions. Inserting a copy of  $(\phi \text{ (make-halt)})$  into the unquoted half of the quine so that it compiles its result (and mirroring this change in the quoted half) yields

```
((lambda ((phi (make-halt))
          (list %0 (list quote %0))))
 (quote (lambda ((phi (make-halt))
          (list %0 (list quote %0)))))
```

which, although not a quine itself, returns a quine when evaluated. Significantly, this quine is not a source code fixed-point of the Skeme interpreter but an object code fixed-point of Dybvig's virtual machine. In effect, it is a quine in a low-level language (phenotype) which reproduces by compiling a compressed self-description written in a high-level language (genotype).

In prior work on evolution of self-replicating programs there has been no distinction between phenotype and genotype; mutations are made on the same representation which is evaluated for fitness. In contrast, in living organisms, small changes in genotype due to mutation can be amplified by a development process and result in large changes in phenotype; it is phenotype which is then evaluated for fitness. In

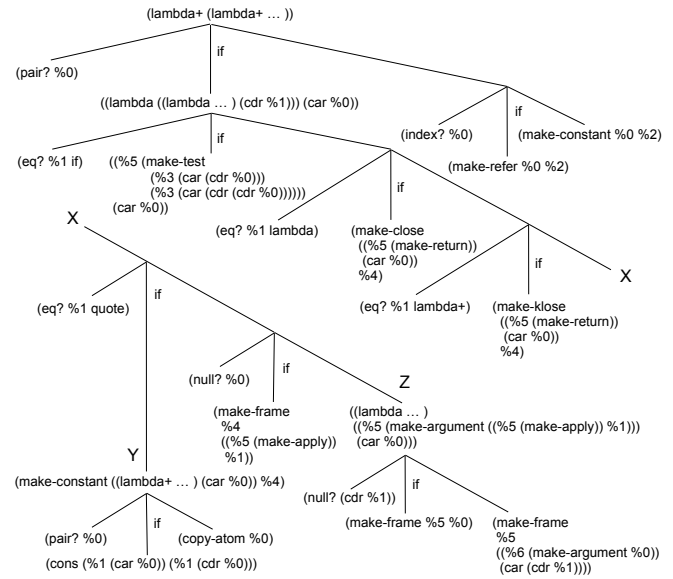

Figure 3: An expression  $\phi$  for compiling Skeme into object code able to compile itself. The X indicates a break in the figure; the subtree labeled Y copies the Skeme source code and the subtree labeled Z compiles function applications.

a compiling quine, small changes in source code (genotype) are amplified by compilation (development) yielding much larger changes in object code (phenotype) and it is object code which determines fitness, since its execution consumes the physical resources of space and time.

### Related Work

(Stephenson et al., 2003) described a genetic programming system which learns priority functions for compiler optimizations including hyperblock selection, register allocation, and data prefetching. (D'haeseleer, 1994) described and experimentally evaluated a method for context preserving crossover. (Kirshenbaum, 2000) demonstrated a genetic programming system where crossover is defined so that it respects the meaning of statically defined local variables.

Several authors have explored the idea of staged or alternating fitness functions. (Koza et al., 1999) used a staged fitness function as a method for multi-objective optimization. (Pujol, 1999) described a system where the fitness function is switched after a correct solution is discovered to a function which minimizes solution size. (Zou and Lung, 2004) and (Offman et al., 2008) used alternating fitness functions to preserve diversity in genetic algorithm derived solutions to problems in water quality model calibration and protein model selection.

### Genetic Programming

Our approach to genetic programming is motivated by the fact that gene duplication followed by specialization of one or both copies is a common route to increased complexity in biological evolution (Finnigan et al., 2012). We introduce

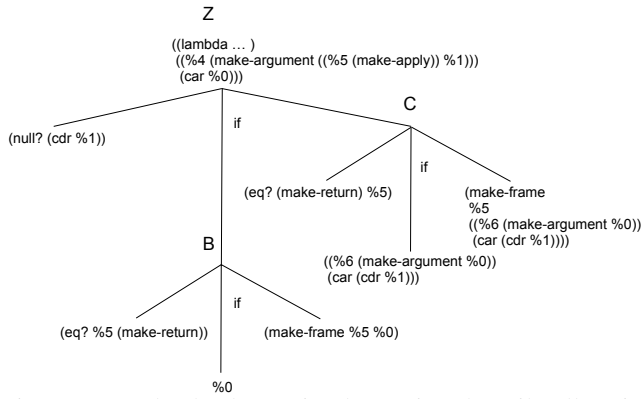

Figure 4: Evolved subtrees implementing the tail-call optimizations which characterize the B and C genotypes. The A genotype performs neither optimization while the D genotype performs both. Both optimizations check to see if the continuation is a return bytecode, which performs a frame stack pop. If so, the push-pop sequence is not generated, resulting in significant savings in time and space usage.

two mutation operators called *bloat* and *shrink* which play roles analogous to gene duplication and specialization and employ these in a genetic programming system where fitness alternates between object code based definitions of complexity and self-replication efficiency. In teleological terms, the bloat operator attempts to increase complexity by adding source code while the shrink operator attempts to increase self-replication efficiency by removing it.

### Alternating Fitness Function

Time is divided into ten generation periods termed *epochs* which alternate between two types, *flush* and *lean*. In flush epochs, fitness is defined as *effective complexity* while in lean epochs it is defined as *self-replication efficiency*.

A test bytecode is defined to be *non-trivial* if both of its continuations are exercised in the course of self-replication. This will only happen if the predicate expression in the *if* special-form from which the test bytecode is compiled sometimes evaluates to true and sometimes to false. The number of non-trivial test bytecodes in the object code is a good measure of the source code's effective complexity. Consequently, in flush epochs the number of non-trivial test bytecodes in the object code is *maximized*.

Because frame stack pushes and pops are the most expensive operation performed by the virtual machine, they are an excellent proxy for overall self-replication cost. Consequently, in lean epochs, the number of frame stack pops, which are implemented by the return bytecode, is *minimized*.

Mutations can be classified as beneficial, neutral, harmful, and lethal. The purpose of the bloat operator is to introduce source code which can be shaped by the shrink operator and by crossover. Significantly, the introduced code does not change the value of any expression which contains

Figure 5: Contour plots of fitness landscapes during flush (left) and lean (right) epochs. Colored arrows point in directions of increased fitness. In lean epochs, the four genotypes A, B, C, and D occupy islands separated by valleys of decreased fitness; the bloat mutations necessary for A to evolve into any of the other genotypes are harmful since they increase the cost of self-replication. In contrast, the shrink mutations required for A to evolve into any of the other genotypes are beneficial. In flush epochs, the situation is reversed—the bloat mutations are beneficial and the shrink mutations are harmful since they increase and decrease effective complexity respectively. Alternating between the two fitness functions creates paths between the A and D genotypes consisting solely of beneficial mutations.

it; it is *value-neutral* with respect to evaluation. Because (by their nature) they increase the cost of self-replication without breaking the compiler, bloat mutations (although never lethal) are harmful during lean epochs.

In contrast, shrink mutations are beneficial when they reverse bloat mutations during lean epochs and can be harmful when they reverse bloat mutations during flush epochs. However, shrink mutations have two different and more pronounced effects. First, a shrink mutation can remove code and break the compiler, in which case it is lethal. Second, it can shape the result of a bloat mutation in a way which decreases the cost of self-replication, in which case it will be strongly beneficial during lean epochs and become fixed in the population.

### Bloat

The source code for the self-hosting compiler contains boolean-valued expressions with six different syntactic forms. Excluding primitive functions, the source code contains six different expressions of constant value. A random syntactic form can be combined with a random de Bruijn index and (if necessary), a random constant-valued expression, to construct a random boolean-valued expression,  $\phi$ .

The bloat operator is defined by five rules. The first four rules define a recursive procedure which applies the bloat operator in selected contexts. The last rule replaces a function application with an *if* expression which returns the same value regardless of whether a random boolean-valued expression,  $\phi$ , evaluates to true or false. Consequently, the

value of the expression is the same before and after the mutation. The fact that the bloat operator is value-neutral with respect to evaluation is important because only viable individuals (those which correctly self-replicate) are copied to the next generation; and although a bloat mutation typically introduces expressions which are not evaluated during self-replication (which greatly reduces the fitness of affected individuals by increasing their self-replication costs) affected individuals always remain viable because bloat mutations cannot actually break the compiler which contains them. The five rules which define the bloat operator are

1.  $(\text{lambda}[+] e_1) \rightarrow (\text{lambda}[+] e'_1)$
2.  $((\text{lambda}[+] e_1) e_2) \rightarrow ((\text{lambda}[+] e'_1) e'_2)$
3.  $(\text{if } e_1 (\text{id } e_2) e_3) \rightarrow (\text{if } e_1 (\text{id } e_2) e_3)$
4.  $(\text{if } e_1 e_2 e_3) \rightarrow (\text{if } e_1 e'_2 e'_3)$
5.  $(f e_1 \dots e_N) \rightarrow (f e_1 \dots e_N) \parallel (\text{if } \phi (\text{id } (f e_1 \dots e_N)) (f e_1 \dots e_N))$

where  $f$  is a primitive function,  $\phi$  is a random boolean-valued expression,  $\text{id}$  is the identity function, and primes mark expressions which are recursively expanded. Alternative right hand sides are separated by vertical bars; the alternative to the left of the  $\parallel$  (no mutation) is chosen with 95% probability; the remaining alternative (mutation) is chosen otherwise. The identity function serves as a value neutral tag in a meta-syntax; because the third rule has the same left and right hand sides, the recursive procedure which applies the bloat operator will not descend into  $\text{id}$  subtrees marked with this tag; this prevents the compounding of bloat mutations.

### Shrink

The rules defining the shrink operator serve two purposes. the first purpose is to reverse mutations introduced by the bloat operator; the fourth shrink rule removes the tagged  $\text{id}$  expressions generated by the bloat operator so that a bloat mutation followed by a shrink mutation (of this type) has no net effect. The second purpose is to simplify function applications; the last shrink rule replaces an expression where a function is applied to one or more values with just one of those values. Because these rules also remove the identity function tags inserted by the bloat operator, the expression which results from a shrink mutation is again subject to bloating. The five rules which define the shrink operator are

1.  $(\text{lambda}[+] e_1) \rightarrow (\text{lambda}[+] e'_1)$
2.  $((\text{lambda}[+] e_1) e_2) \rightarrow ((\text{lambda}[+] e'_1) e'_2)$
3.  $(\text{if } e_1 e_2 e_3) \rightarrow (\text{if } e_1 e'_2 e'_3)$
4.  $(\text{if } e_1 (\text{id } e_2) e_3) \rightarrow (\text{if } e_1 (\text{id } e'_2) e'_3) \parallel e_2 \mid e_3$
5.  $(f e_1 \dots e_N) \rightarrow (f e_1 \dots e_N) \parallel e_1 \mid \dots \mid e_N$

Table 1: Complexities and self-replication costs.

	A	B	C	D
non-trivial tests	8	9	9	10
returns	551	333	432	183

where  $f$  is a primitive function,  $\text{id}$  is the identity function, and primes mark expressions which are recursively expanded. Alternative right hand sides are separated by vertical bars; the alternative to the left of the  $\parallel$  (no mutation) is chosen with 95% probability; one of the remaining alternatives (mutation) is chosen otherwise (each with equal probability). Unlike the bloat operator, which is value neutral, the shrink operator changes the object code generated by the compiler when it modifies an expression which is evaluated during self-replication. In the case of the fourth shrink rule, this often reverses a harmful bloat mutation, in which case the shrink mutation is beneficial. However, in the case of the last shrink rule, the mutation most often breaks the compiler. Very rarely, the shrink mutation does not break the compiler but instead results in a decrease in self-replication cost.

The problem which plagues many genetic programming systems, in which code trees grow larger with increasing time, does not occur for two reasons. First, the use of the  $\text{id}$  function as a tag prevents the bloat operator from being applied within  $\text{id}$  expressions which were themselves just created. Second, the shrink operator reverses bloat mutations, and bloat mutations not yielding a decrease in self-replication cost are strongly selected against during lean epochs.

The combined effect on fitness of these two mutation operators is complex. After a pair of bloat and shrink mutations, a more complex source code must be analyzed by a more complex compiler, a change which might (but more likely will not) pay for itself by an increase in the efficiency of the generated object code.

### Crossover

Because the self-hosting compiler is a complex lexically scoped program, variables which are defined in one scope will not necessarily be defined in other scopes. If we employed the standard method of non-homologous crossover used in most work on genetic programming, then subtrees could be inserted into scopes where one or more variables are undefined, and this would break the compiler. We address this problem by employing the *homologous* crossover method described by (D'haeseleer, 1994). In this method, the crossover operator descends into both parent trees in parallel; points where the two parent trees differ are subject to crossover, with the child receiving the subtree of either parent with equal probability. D'haeseleer notes that homologous crossover facilitates convergence (fixation) since children resulting from the crossover of identical parents will also be identical to the parents.

Figure 6: The median number (in a population of size 200) of non-trivial test bytecodes averaged over 20 runs (error bars show plus or minus one standard deviation). Because each non-trivial test bytecode results from a bloat mutation at a distinct point in the  $\varphi$  expression, this graph demonstrates that mutation is in no way restricted to the two points relevant to the evolution of tail-call optimization.

## Genotypes

Function applications involving one and two arguments are compiled at two different points in the  $\varphi$  expression and each of these points is a potential target for a pair of bloat and shrink mutations which would partially implement tail-call optimization. We call the genotype of programs which perform neither optimization *A*, one (or the other) optimization *B* (or *C*), and both optimizations, *D*. Both optimizations check to see if the continuation is a return bytecode, which performs a frame stack pop. If so, the push-pop sequence is not generated, resulting in significant time and space savings. See Figure 4. Lower bounds for the complexity and self-replication cost of each of the four genotypes are shown in Table 1. Finally, the relative fitnesses of the four genotypes are shown graphically, in the context of the fitness landscapes for the flush and lean epochs, in Figure 5.

## Experimental Results

The initial population consisted of two hundred identical individuals of genotype *A* at the beginning of a flush epoch (in which fitness is equated with effective complexity). In the first step of the genetic algorithm, the bloat and shrink operators are applied to all individuals in the population and the mutants which result are tested for viability. To test for viability, the mutant is evaluated to produce a daughter, and the daughter is evaluated to produce a granddaughter. The mutant is classified as viable if the daughter and granddaughter contain the same number (greater than zero) of bytecodes (this is done in lieu of a much more expensive test of actual structural equivalence). Viable mutants replace their pro-

Figure 7: The median number (in a population of size 200) of return bytecodes executed during self-replication averaged over 20 runs (error bars show plus or minus one standard deviation).

genitors in the population.

The population is then subjected to crossover using tournament selection. In each tournament, four individuals are chosen at random (with replacement). The winners of two tournaments are then combined using crossover, and the resulting individual is tested for viability. The crossover operation is repeated until it yields two hundred viable individuals which comprise the population of the next generation.

The above process is repeated for nine more generations, then the epoch is switched to lean (in which fitness is equated with self-replication efficiency). The genetic algorithm is run for a total of 100 generations (five flush epochs interrupted by five lean epochs).

In an initial experiment, the system was run twenty times. The median number of interesting test bytecodes contained in the compiled  $\varphi$  expression and the median number of return bytecodes executed during self-replication were then plotted as a function of generation; see Figures 6 and 7. As expected, both complexity and self-replication cost increase in flush epochs and decrease in lean epochs. After 40 generations (two flush-lean cycles), the median complexity at the end of flush epochs is nearly double its initial value, which means that the majority of individuals contain 7 or more predicates which compile to non-trivial test bytecodes not present in the initial population. Furthermore, the median complexity at the end of lean epochs is always 10 or more, which suggests that either 1) the shrink operator is not fully able to reverse the effects of the bloat operator so that one or more bloat mutations (on average) survive through lean epochs; or 2) one (or both) of the *B* and *C* alleles is fixed in the population. Examination of Figure 7 shows that after 40 generations, the median self-replication cost at the end of lean epochs is slightly more than half of its initial value.

This is consistent with evolution of one or both of the B and C genotypes. Self-replication cost continues to increase and decrease (depending on epoch) eventually reaching a point where the median value at the end of the fifth lean epoch is nearly three times smaller than the initial value. This is consistent with the evolution of the D genotype.

After running the system 100 times, the probabilities of the B, C, and D genotypes evolving and for the mutations becoming fixed in the population were estimated. See Table 2. Notably, the most complex and most efficient genotype, D, evolved within 100 generations 81 times. Additionally, the average and median number of generations required for each genotype to evolve and for the mutations to become fixed were also estimated. Considering only the 81 runs in which the D genotype evolved, the average number of generations required was approximately 36 and the median number was 29.

Table 2: Generation of initial evolution and fixation.

	B	C	D	B'	C'	D'
probability	0.90	0.91	0.81	0.89	0.78	0.70
mean	21.8	24.5	35.8	29.9	34.3	43.3
std. dev.	21.0	22.0	24.5	21.1	22.2	24.5
median	11	13	29	17	33	36

If we know the average numbers of individuals of a given genotype in each generation, then we can compute cumulative distribution functions for evolution and fixation of that genotype; see Figure 8. If we examine the c.d.f.'s we see several interesting things.

First, the c.d.f.'s for evolution of genotypes have zero slope during lean epochs, which suggests that new genotypes typically appear during flush epochs, when fitness is equated with effective complexity. Conversely, the c.d.f.'s for genotype fixation have zero slope during flush epochs, which leads us to conclude that fixation of genotypes typically occurs during lean epochs, when fitness is equated with efficiency. This is consistent with an increase in diversity during flush epochs and a decrease during lean epochs.

Second, there is always a lag between the generations of evolution and fixation, and the size of the lag depends on the improvement in self-replication efficiency—the greater the improvement, the shorter the lag. The C allele (which confers an advantage of 119 returns relative to the A allele) requires more time for fixation than the B allele (which confers an advantage of 218 returns).

If we know the generation in which each genotype evolved, it is possible to estimate probabilities for each of the pathways leading from the (least complex and least efficient) A genotype to the (most complex and most efficient) D genotype; see Table 3. This analysis shows that in 64% of the runs in which D evolved, one of the B or C alleles evolved and was fixed prior to the evolution of the other;

Table 3: Probabilities of pathways to D genotype.

$t_B < t_C = t_D$	$t_C < t_B = t_D$	$t_B < t_C < t_D$	$t_C < t_B < t_D$
0.33	0.31	0.26	0.09

the D genotype then evolved by mutation from an ancestral program of the B or C genotype. However, in 35% of the runs in which D evolved, something (arguably) more interesting happened. Namely, the B and C alleles evolved in distinct lineages before either was fixed. The D genotype then evolved when an individual with the B allele and an individual with the C allele were combined by crossover. Stated differently, in 35% of the runs where D evolved, beneficial traits which evolved separately were combined by crossover to produce a child program more complex and more efficient than either parent program.

### Future Work

This paper describes work that, although preliminary, opens many avenues for further exploration, including

- Determining whether or not a self-replicating program which reproduces by compiling itself can evolve the optimum order for the tests comprising the decision tree which performs syntactic analysis; this would require a new mutation operator which can reorder nested-*if* expressions.
- Determining whether or not it is possible to evolve dead code elimination, which would be a useful optimization in a system which includes mutation operators (like bloat) which (in effect) introduce dead code; to accomplish this, the bloat operator would have to generate a much larger set of  $\phi$  expressions, including dereferencing source code with *car* and *cdr* combinations.
- In the present system, de Bruijn indices are used mainly to simplify the compilation process by eliminating the need for static analysis; however, it is difficult to see how new lexical scopes could evolve (via a new mutation operator which introduces *lambda* expressions) unless bound variables are represented by symbols, and this would mean that the self-hosting compiler must be generalized so that it performs static analysis.
- Demonstration of *auto-constructive evolution* as described by (Spector and Robinson, 2002), in which artificial organisms possess not only their own means of self-replication, but also of producing variation; this would require coding all mutation operators in Skeme and including this code in the subtree of the self-hosting compiler which copies quoted expressions.
- Reification of the compiling quine as a self-replicating distributed virtual machine (including the items listed above) and demonstration of evolution of increased complexity and self-replication efficiency by reified artificial organisms.

Figure 8: Cumulative distribution functions representing the probabilities that genotypes B, C, and D have evolved and are fixed by the given generation.

## Conclusion

We introduced a new type of self-replicating program which (unlike previous self-replicating programs) includes distinct phenotype and genotype components. Although the program is encoded in machine language, and (for this reason) can be executed on a CPU (or reified as a distributed virtual machine) it reproduces by compiling itself from its own source code, which is written in a more expressive high-level language. Because compiling is an intrinsically more complex process than copying, there is a much larger space of implementations to be explored by an evolutionary process; because its genotype is encoded in a high-level language, the space of neighboring self-replicating programs can be more efficiently probed.

To address the problem of how a complicated lexically scoped program like a compiler can evolve into a more complex and efficient program without breaking, we designed, implemented and tested a novel genetic programming system, which uses a pair of mutation operators analogous to gene duplication and specialization, together with homologous crossover and an alternating fitness function which selects for complexity or efficiency depending on epoch. Using this system, we experimentally demonstrated the evolution of several self-replicating programs of increased complexity and efficiency from a less complex and less efficient ancestor. We were able to show that in a population of 200 individuals, the most complex and efficient self-replicating program evolved within 100 generations in over three quarters of all trials, and by crossover of less complex and less efficient parent programs a significant fraction of the time.

### Abstract

With the development of high-throughput technologies, monitoring biological systems comprehensively has become feasible and affordable. However, the transition from high-throughput data to the underlying biology of various phenotypes remains challenging. Pathway analysis identifies biological processes that are associated with a particular phenotype, which provides insights into the underlying biological mechanisms. Therefore, pathway analysis has become a popular tool for analyzing high-throughput data. Most existing pathway analysis methods are based on a simple assumption that pathways act in isolation whereas they cooperate with each other in a complex manner. In this study, we focus on pathway interactions that are associated with bladder cancer risk. We identify disease-specific pathway-pathway interactions based on SNP-SNP interactions and gene-gene co-expression relationships. By analyzing the structure of pathway interaction networks, we highlight the “central” pathways that should be further studied.

### Introduction

Techniques such as high-throughput sequencing and gene/protein profiling have transformed biological research by enabling comprehensive monitoring of a biological system (Khatri et al., 2012). Conventional analyses of high-throughput data usually test the association of individual genes/proteins with a given phenotype. Although successfully applied in many studies, this approach fails to provide insights into the underlying biological mechanisms of the phenotype being studied. As an alternative approach, pathway analysis highlights the risk associated biological processes. The mechanisms of pathway associations can be used for developing strategies to diagnose, treat and prevent complex diseases (Ramanan et al., 2012), which makes high-throughput datasets more often viewed as a foundation to discover associated pathways (Hirschhorn, 2009).

In pathway analyses, gene sets corresponding to biological pathways are tested for significant associations with a phenotype. Multiple methods have been developed and among them pathway enrichment approach is the most popular one. Most pathway-enrichment-approach studies follow two categories: the threshold-based framework and the

rank-based framework. Threshold-based approaches usually statistically evaluate the fraction of genes in a particular pathway among all the significant markers (Boyle et al., 2004). Rank-based approaches rank all markers based on their significances and then look for pathways that have better rankings than the overall distribution (Subramanian et al., 2005). Although successfully applied in many studies, enrichment approaches depend on single-marker statistics and treat each gene independently. In reality, biological systems are driven by complex biomolecular interactions instead of individual genes (Schadt et al., 2009). Thus, methods that take biomolecular interactions into account remain needed.

Most pathway analysis approaches assume that each pathway is independent of the others, which could be problematic (Khatri et al., 2012). Pathways do not operate in isolation. Instead, they cooperate and work together as a unit. A recent study of yeast showed that rewiring of genetic interactions in response to DNA damage are more likely to occur among pairs of genes that belong to two different biological processes (Bandyopadhyay et al., 2010). Although whether interactions are more likely to occur within the same pathway or across different pathways in human is unknown, the significance of pathway interactions is in-negligible. There are several possible ways two pathways can interact: sharing components (Lu et al., 2007), components physically interacting with counterparts from the other pathway (Lu et al., 2007; Guo and Wang, 2009), components relating with components of the other pathway via transcription (Guo and Wang, 2009), etc. The different interacting ways can be reflected in different manners including pathway overlapping, direct or indirect protein protein interactions (PPIs), co-regulation of genes etc. So to fully understand pathway interactions, integration of knowledges from different levels is required.

Several studies have been done to address pathway interactions. Tong et al. carried out genetic screening and used synthetic lethality of two mutations to indicate interaction between two pathways (Tong et al., 2004). Later, Kelley et al. used such genetic interactions to link “pathways”, which is defined as sets of densely connected pro-

teins in the protein-protein-interaction (PPI) network (Kelley and Ideker, 2005). Meanwhile, overlapping in genes, proteins or metabolite contents between pathways has also been used to gain insights in possible relationships between pathways (Isserlin et al., 2010). Lastly, a function based approach is to find possible pathway crosstalks by looking at protein interactions between pathways (Li et al., 2008). Most previous methods highlight pathway crosstalks under general conditions. The crosstalks identified are not associated with any particular phenotype. In this study, we make use of the disease case-control data and search for the disease specific pathway interactions only, which distinguish our work from previous ones the most.

Meanwhile, network science has emerged as a useful tool for modeling biological interactions and dependencies (Ideker and Sharan, 2008). Compared to analysis of groups of distinct objects, networks provide more information on the relatedness and interconnectivity of them, which makes network a suitable framework for investigating pathway interactions.

In this study, we focus on pathway interactions that are associated with bladder cancer risk. We infer pathway interaction networks from two different levels: SNP-SNP interactions and gene-gene co-expression relationships. By analyzing the structure of pathway interaction networks, we identify essential pathways that hold great potentials for future studies.

## Methods

### SNP interaction network

A recent study characterized the space of pairwise interactions in a population-based bladder cancer association study (Hu et al., 2011). In their SNP interaction network, each vertex corresponds to a single nucleotide polymorphism (SNP). An edge linking a pair of vertices corresponds to an interaction between two SNPs. Weights assigned to each SNP and each pair of SNPs quantify how much of the disease status the corresponding SNP and SNP pair can explain. The significance of the SNP interaction network is not limited to single main or interaction effects. Instead, it describes the overall significance of the global interaction structure, which makes this approach systematic. To identify bladder cancer specific pathway interactions, we adopt the SNP interaction network from this previous study and the network is shown in Figure 1.

### Dataset

The microarray dataset used in this study is publicly available from Gene Expression Omnibus (GEO) website (dataset ID: GDS1479) and more details about this dataset can be obtained at Dyrskjot et al. (2003). Briefly, the original study profile about 22,000 genes to analyze bladder biopsies of superficial transitional cell carcinomas with or without surrounding carcinoma in situ (CIS) lesions and muscle

invasive carcinomas (mTCC). To match disease stages of individuals in the bladder cancer SNP dataset, we only use two out of the five groups in the original study. One group contains 15 tumor biopsies from superficial transitional cell carcinoma (sTCC) without surrounding CIS, which serves as cases. The other group contains 9 biopsies of normal bladder mucosa from patients without a bladder cancer history, which serves as controls. The cRNA from different samples are hybridized to Affymetrix U133A GeneChips. After data processing as described by Dyrskjot et al. (2003), there are about 22,000 genes in the dataset.

### Differential co-expression network

Genes with similar expression patterns may form complexes, pathways, or participate in regulatory and signaling circuits (Eisen et al., 1998; Ideker et al., 2002; Huang et al., 2007). Therefore, gene co-expression networks, which describe the pairwise relations among gene expression profiles, have become a popular tool for microarray analysis. A gene co-expression network is an undirected graph, where the vertices correspond to genes, and edges between genes represent significant co-expression relationships (Stuart et al., 2003). The weight of an edge can be computed using different correlation measures and an edge is included in the network if its weight pass a certain pre-specified threshold.

Gene co-expression networks have been successfully applied in many studies mostly to identify functional gene modules (Stuart et al., 2003; Presson et al., 2008; Weston et al., 2008). However, to study a particular disease, it is the difference between cases and controls that provides the most information about the underlying mechanism. In other words, rather than asking ‘what parts of the system are the most abundant or dominant’, we should ask ‘What parts of the system are most distinctive between different conditions’ (Ideker and Krogan, 2012). Therefore, to gain insights into the transition from healthy individuals to bladder cancer patients, we adapt the framework of the differential network previously proposed (Bandyopadhyay et al., 2010). Instead of constructing two static co-expression networks, one for cases and one for controls, we build differential co-expression networks to describe the changes of pairwise relations among genes from controls to cases. In this way, co-expressions present in both conditions are downplayed or removed from the differential network. The co-expressions that reflect the changes from controls to cases are distinguished from those that support the housekeeping functions.

Specifically, we filter the probes in the microarray dataset and only 308 of them, which also exist in the SNP dataset, are considered in this section. We compute Spearman’s correlation for all  $\binom{308}{2} = 47,278$  pairs of transcripts separately in cases ( $C_{\text{case}}$ ) and controls ( $C_{\text{controls}}$ ). Pairwise differential co-expression is calculated as  $C_{\text{case}} - C_{\text{control}}$  and assigned to the corresponding edge as its weight. The negative

differential co-expression network is constructed to include only edges with significant negative weights and the positive differential co-expression network only include edges with significant positive weights. In other words, the negative differential co-expression network describes the gene pairs which lose correlations from controls to cases, while the positive differential co-expression network describes those which gain correlations.

### Pathway interaction network

We construct pathway interaction network  $G_1$  from SNP interaction network,  $G_2^-$  from negative differential co-expression network and  $G_2^+$  from positive differential co-expression network. In all pathway interaction networks, a vertex represents a pathway. Two pathways are connected if there are more edges than by chance between the two corresponding pathways in the underlying biomarker network.

For example, to construct pathway interaction network  $G_1$ , we use permutation test to determine whether edges are more likely to occur between two pathways than by chance in the SNP interaction network. First, we annotate all the vertices in the SNP interaction network with their functions using canonical pathway annotations from MsigDB collection 2. All SNPs in this dataset are within coding region, so a SNP-to-gene-to-pathway mapping is straight forward. To investigate the enrichment of pathway-pathway interactions, we count the frequency of edges in the SNP interaction network between two particular pathways. Note that pathways with more SNPs might display more edges in the SNP interaction network. To control the bias introduced by pathway sizes, we use permutation test to generate a null distribution. Specifically, we randomly shuffle the SNP-pathway(s) annotations for 1,000 times and assess the frequency of edges between two particular pathways in the original SNP interaction network at each time. The  $P$ -value of a pathway-pathway interaction enrichment is computed as the fraction of corresponding edge frequencies on permuted data which are no smaller than that of the real data. Similarly, pathway interaction networks  $G_2^-$  and  $G_2^+$  are generated based on the negative and positive differential co-expression networks accordingly. In all three cases, a pathway pair is included in the pathway interaction network if the  $P$ -value of the pathway-pathway interaction enrichment is smaller than 0.001.

### Essential vertices identification

To identify key vertices in the networks, we use bottleneck vertices to survey independent regulation as it has been shown that bottleneck vertices are regulated in a condition-dependent manner in biological networks (Yu et al., 2007). We define bottleneck vertices as vertices with the 10 highest betweenness centrality scores. The betweenness centrality score is based on the number of shortest paths that cross a given vertex, and thus reflects how embedded (i.e. central) a vertex is in the network (Freeman, 1977).

Hubs, highly connected vertices in other words, play an integral role in maintaining network integrity and in mass information transfer. Therefore, we also identify hubs of the networks. In this study, we define hub vertices as vertices with the 10 highest degree scores.

Both hub and bottleneck vertices have been associated with functional essentiality (Yu et al., 2007; Zotenko et al., 2008). We are interested in their ability to influence the propagation of signals across the network and their importance to maintain the integrity of the network. Particularly, we define hub-bottleneck vertices as the overlapping vertices between hub vertices and bottleneck vertices.

## Results

### Pathway interaction network derived from SNP interaction network

We study whether SNP-SNP interactions are more likely to occur between certain pathway pairs or not. As described previously, we construct pathway interaction network  $G_1$  by only including pathway pairs which have more edges between them in the SNP interaction network than by chance ( $P < 0.001$ ). Figure 2 shows the structure of pathway interaction network  $G_1$ .  $G_1$  has 386 vertices and 635 edges. There are two connected components in the network and the vertices cluster into several communities. Moreover, there is no self-loop in  $G_1$ , which indicates that SNP-SNP interactions mostly happen between different pathways instead of within the same pathway.

A heavy-tail degree distribution of  $G_1$  indicates the existence of hub vertices. The hub-bottleneck vertices (pathways) are reported in Table 1. Among all the hub vertices, KEGG\_FOCAL\_ADHESION is connected to 269 neighbors and displays the highest betweenness centrality.

Pathway	Betweenness Centrality	Degree
KEGG_FOCAL_ADHESION	0.93	268
BIOCARTA_VITCB_PATHWAY	0.11	32
KEGG_STEROID_HORMONE_BIOSYNTHESIS	0.09	13

REACTOME_TELOMERE_MAINTENANCE	0.02	10

Table 1: Hub-bottleneck vertices (pathways) in pathway interaction network  $G_1$  derived from SNP interaction network. Pathways are ranked in descending order of betweenness centrality.

### Differential co-expression network

To study the bladder cancer specific co-expression patterns, we construct differential co-expression networks from the microarray dataset. To match the SNP dataset, only 308 transcripts that also exist in the SNP dataset are used in this section. The changes of Spearman correlation between all

$\binom{308}{2} = 47,278$  pairs of transcripts from controls to cases are shown in Figure 3. The differential co-expression correlation,  $(C_{\text{case}} - C_{\text{control}})$ , follows a normal distribution with  $\text{mean} \pm \text{stdv} = 0.0006 \pm 0.51214$ . The 95% confidence interval is  $[-1.003, 1.004]$ . Transcript pairs with  $C_{\text{case}} - C_{\text{control}} < -1.003$  are included in the negative differential co-expression network, which means that there are co-expressions in controls but not in cases. Similarly, transcript pairs with  $C_{\text{case}} - C_{\text{control}} > 1.004$  are included in the positive differential co-expression network, which indicates that there are co-expressions in cases but not in controls.

The negative differential co-expression network has 297 vertices and 1,114 edges. Among two connected components, the largest one has 293 vertices. Similarly, the positive differential co-expression network possesses 287 vertices and 1,114 edges. There are no isolated islands in the network. Both differential co-expression networks display a heavy-tail degree distribution, which indicates the existence of hub genes.

To identify the key players for maintaining network integrity and signal propagation across the network, we identify the hub-bottleneck vertices in both negative and positive differential co-expression networks (Table 2). Interestingly, gene GATA3, ERBB2 and HFE are identified in both differential co-expression networks.

Gene	Betweenness Centrality	Degree
GATA3	0.21	67
MSH2	0.13	47
ERBB2	0.07	31
HFE	0.04	23
HADHA	0.04	21
LIG1	0.03	26

Gene	Betweenness Centrality	Degree
HFE	0.13	37
FZD7	0.09	26
FOXC1	0.06	53
ERBB2	0.06	27
GATA3	0.06	28

Table 2: Hub-bottleneck vertices (genes) in negative (top) and positive (bottom) differential co-expression networks. Genes are ranked in descending order of betweenness centrality.

### Pathway interaction network derived from differential co-expression network

We investigate whether edges in the differential co-expression networks are more likely to occur between particular pathway pairs than by chance. As described previously, we construct pathway interaction network  $G_2^-$  by only including pathway pairs which have more edges between them in the negative differential network than by chance ( $P < 0.001$ ). Similarly, pathway interaction network  $G_2^+$  is obtained from the positive differential co-expression network.

As shown in Figure 4, pathway interaction network  $G_2^-$  has 78 vertices and 100 edges. There are three connected

components and the entire network divide into several communities. The hub-bottleneck vertices (pathways) are reported in Table 3. Meanwhile, pathway interaction network  $G_2^+$  has 70 vertices and 83 edges. The network has six connected components (Figure 5). Surprisingly, no common edge is shared by  $G_2^-$  and  $G_2^+$ . This means that when comparing cases with controls, the gaining of co-expression and the loss of co-expression happen between different pathway pairs.

Although  $G_2^-$  and  $G_2^+$  do not share any common edge, the essential vertices in the two networks overlap with differences (Table 3). Two pathways, BIOCARTA\_GATA3\_PATHWAY and KEGG\_MELANOGENESIS, are identified as hub-bottleneck vertices in both networks.

It is also an interesting thing that there is no self-loop in  $G_2^-$  (Figure 4) and only two self-loops are observed in  $G_2^+$  (Figure 5). In other words, no pathway possesses more edges within itself than by chance in the negative differential co-expression network. Only two pathways, REACTOME\_GPCR\_LIGAND\_BINDING and SA\_CASPASE\_CASCADE, have more edges within themselves than by chance in the positive differential co-expression network. This indicates that differential co-expressions seem to happen mostly between different pathways rather than within the same pathway.

Pathways	Betweenness Centrality	Degree

Table 3: Hub-bottleneck vertices (pathways) in pathway interaction networks  $G_2^-$  (top) and  $G_2^+$  (bottom). The two pathway interaction networks are derived from negative (top) and positive (bottom) differential co-expression networks accordingly. Pathways are ranked in descending order of betweenness centrality.

## Discussion

We have identified pathway-pathway interactions that are associated with bladder cancer risk. Specifically, we investigate pathway interaction at two levels: genetic inter-

actions and co-expression relations. We construct one pathway interaction network from the SNP interaction network and two from the differential co-expression networks. There are some limitations to our approach that are worth highlighting. First, there are multiple other ways pathways can interact with each other, i.e. through sharing common components. Examining pathway relationships more thoroughly at different levels would be helpful. Second, co-expression relationships are transferable. In other words, if two genes are both correlated with a third gene, a correlation will be observed between those two genes. Using partial correlation instead of correlation itself might be helpful to identify direct gene-gene co-expression relationships (de la Fuente et al., 2004).

Despite these limitations, our analyses have helped to identify the pathway interactions that are associated with bladder cancer risk and highlight the importance of pathway interactions. In our study, we observe several interesting aspects and discuss them as follows.

First, we characterize the differential co-expression relationships between cases and controls. The hub-bottleneck genes are identified in the differential co-expression networks. Three genes, GATA3, ERBB2 and HFE, are recognized in both positive and negative differential co-expression networks. Gene GATA3 encodes trans-acting T-cell-specific transcription factor GATA-3, which is an important regulator of T-cell development and plays an important role in endothelial dysplasia. Previously, GATA3 has been suggested as a marker of urothelial differentiation (Higgins et al., 2007; Miyamoto et al., 2012). The fact that GATA3 appears as a hub-bottleneck gene in both positive and negative differential co-expression networks (Table 2) suggests that GATA3 could be actively turning on or off its neighbor genes' expression, which might be highly associated with bladder cancer risk. Whether GATA3 is causing the expression level changes of its neighbor genes and how its neighbor genes contribute to the disease risk should be further studied. Gene ERBB2 encodes a member of the epidermal growth factor (EGF) receptor family of receptor tyrosine kinases. Tumor-specific overexpression of ERBB receptors or their isoforms has been reported in a previous study (Junttila et al., 2003). Whether and how ERBB2 influences its neighbor genes' expressions in the context of bladder cancer risk should be explored. Gene HFE encodes a membrane protein HLA-h, which binds to transferrin receptor (TFR) and reduces its affinity for iron-loaded transferrin (Feder et al., 1998). Whether and how HFE is associated with bladder cancer risk remains unknown. The central role of HFE in the differential co-expression networks might reflect its association with bladder cancer risk.

Second, traditional pathway analyses focus on identifying pathways that are enriched for significant biomarkers. We took a different route and look for pathway pairs that are enriched for between-pathway SNP-SNP interac-

tions or between-pathway differential co-expressions. Consequently, we identify pathways that are "central" in the whole system instead of pathways that are individually associated with the disease risk. We run Gene Set Enrichment Analysis (Subramanian et al., 2005) on both the SNP dataset and the microarray dataset. Most of the pathways reported in Table 1 and 3 are not enriched in the significant biomarkers. However, existing knowledge indicates that some of them could be highly involved in the underlying mechanisms of bladder cancer. For instance, two telomere related pathways are identified as hub-bottleneck vertices in  $G_1$  (Table 1). It is well known that telomere dysfunction or loss can cause sister-chromatid fusions that is associated with oncogene amplification (Campbell et al., 2010; Murnane, 2012).

Third, it is interesting that all networks constructed in this study possess a heavy-tail degree distribution. In other words, most vertices in the networks have only few neighbors whereas a few vertices have many neighbors. This structure makes the network robust to random removal of vertices and vigorous to external perturbations (Barabasi and Bonabeau, 2003; Wang and Chen, 2002). Scale-free structures have been observed in various biological networks (Jeong et al., 2001; Li et al., 2004). It is interesting that we observe a similar structure at the pathway level.

Fourth, we find that the pathway interaction network  $G_1$  does not share any common edge with  $G_2^+$  or  $G_2^-$ . The hub-bottleneck vertices in  $G_1$  are not as "central" in  $G_2^-$  or  $G_2^+$ . Although genetic interactions are very different with co-expression patterns, this result is still surprising. This means that the interactions across pathways are of distinguishing patterns at different levels.

Last, we find that both SNP-SNP interactions and differential co-expressions mostly happen between different pathways rather than within the same pathway. This result suggests that SNP interactions and co-expression patterns in known pathways stay stable across cases and controls. It is the SNP interactions and co-expression patterns between these pathways that are reprogrammed across different disease conditions. Previous studies in yeast have shown that static genetic interactions are enriched within known pathways (Kelley and Ideker, 2005), whereas differential genetic interactions are much more likely to occur among pairs of genes connecting two different pathways than among pairs of genes within the same pathway (Bandyopadhyay et al., 2010). Although co-expressions do not necessarily indicate genetic interactions, it is still encouraging to observe similar results in human SNP and microarray data in our study. Also, this observation further emphasizes the important role of pathway interactions in disease association studies, which highlights the significance of our work.

In summary, we construct bladder cancer specific pathway interaction networks from both SNP-SNP interactions and gene-gene co-expression patterns. Our study highlights key pathway interactions that should be further investigated

and emphasizes the importance of disease-specific pathway interactions.

Figure 1: SNP interaction network. A vertex represents a SNP and an edge represents the interaction between the two vertices it connects. The weight of an edge reflects the pairwise interaction strength. There are 319 vertices and 255 edges in the SNP interaction network. The 319 SNPs cover 185 genes. The width of an edge and the size of a vertex are proportional to their weights. More details about this network are available at Hu et al. (2011)

Figure 2: Pathway interaction network  $G_1$  revealed by SNP interaction network. A vertex represents a pathway and an edge exists if the number of SNP interactions between the two corresponding pathways is significantly larger than by chance ( $P < 0.001$ ). There are 386 vertices and 635 edges in the network. The largest connected components has 384 vertices. The network shows a heavy tail degree distribution.

Figure 3: Frequency distribution of pairwise differential co-expression,  $C_{\text{case}} - C_{\text{control}}$ . Spearman correlation for all 47,278 pairs of genes are calculated for cases ( $C_{\text{case}}$ ) and controls ( $C_{\text{control}}$ ) separately and the difference ( $C_{\text{case}} - C_{\text{control}}$ ) are presented.  $C_{\text{case}} - C_{\text{control}}$  ranges from -1.652 to 1.711 and follows a normal distribution. Red lines represent the 95% confidence interval ( $C_{\text{case}} - C_{\text{control}} = -1.003$  and 1.004 respectively). There are 1,011 pairs of transcripts on the left 2.5% tail and 1,114 on the right 2.5% tail.

Figure 4: Pathway interaction network  $G_2^-$  revealed by negative differential co-expression network. A vertex represents a pathway and an edge exists if differential co-expression are more likely to occur between the two pathways it connects than by chance in the negative differential co-expression network. The network  $G_2^-$  has 78 vertices and 100 edges.

Figure 5: Pathway interaction network  $G_2^+$  revealed by positive differential co-expression network. A vertex represents a pathway. An edge indicates that there are more edges between the two pathways it connects than by chance in the positive differential co-expression network. There are 70 vertices and 83 edges in the network. The vertices fall into six connected components.

# Information Aggregation Mechanisms in Social Odometry

## Abstract

Multi-robot exploration and navigation is a challenging task, especially within the swarm robotics domain, in which the individual robots have limited capabilities and have access to local information only. An interesting approach to exploration and navigation in swarm robotics is *social odometry*, that is, a cooperative strategy in which robots exploit odometry for individual navigation, and share their own position estimation through peer-to-peer local communication to collectively reduce the estimation error. In this paper, the robots have to localize both a home and a goal location and navigate back and forth between them. The way in which navigational information is aggregated influences both the efficiency in navigation between the two areas, and the self-organized selection of better paths. We propose three new parameter-free mechanisms for information aggregation and we provide an extensive study to ascertain their properties in terms of navigation efficiency and collective decision.

## Introduction

Navigation is a basic task for robots in most application domains, would that be for cleaning a room or demining a field. In few cases, the environment is completely known in advance, and therefore a detailed navigation plan can be produced. Most often, the environment is not completely known and exploration is required to identify and reach the desired locations. When multiple robots explore an unknown environment, cooperative strategies can be used to improve exploration and navigation efficiency. This is particularly useful in the swarm robotics domain, in which individual robots cannot rely on global information or complex algorithms (Brambilla et al., 2013). In this paper, we study a cooperative exploration and navigation strategy based on the peer-to-peer exchange of information among robots in a swarm. We propose three variants of the information aggregation mechanism, and we investigate their impact over the dynamics of navigation of the swarm as well as the resulting efficiency with respect to an exploration and exploitation task.

Exploration and navigation strategies in swarm robotics should present a low complexity to match the limited capabilities of the individual robots. The simplest way to explore

and navigate in a closed area is through random walk. While not being the most efficient way, it assures that the robots reach every part of the environment, even if this may require a long time. In order to improve over a purely random exploration, the robots can memorize and map their surroundings to avoid previously explored zones (Thrun, 2008) to reach specific areas of interest. To this purpose, the robot can position itself on the map and navigate in the environment using dead-reckoning techniques such as odometry. Odometry relies on the integration over time of the movement vector—as perceived through the robot (proprioceptive) sensors—in order to maintain an estimate of the robot position. However, this approach is quite error prone since estimation errors are cumulated over time, therefore requiring techniques for error reduction such as Kalman filters (Thrun et al., 2005).

Alternatively, the estimation error can be reduced through the shared effort of multiple robots exchanging structured information (Martinelli et al., 2005). By sharing the estimated position of a landmark, the robots can collectively reduce the overall odometric error. This is a straightforward mechanism that easily lends itself to implementation on very simple robots. Therefore, the collective reduction of odometry errors can be instantiated also in swarm robotics contexts, as it complies with the inherent limitations of the robots. This mechanism was first introduced by Gutiérrez et al. (2009) and is referred to as *social odometry*. In this approach, the robots estimate the navigation path between two target areas in the environment (*i.e.*, home and goal locations) using odometry and attach to this estimate a confidence level that decreases with the distance travelled. At the same time, the robots share their navigation information within the swarm in a local peer-to-peer manner. Thanks to this process, information about target areas spreads gradually within the swarm, contributing to reduce the error in the position estimation. Overall, this decentralized process results in an increased efficiency in the swarm navigation abilities.

An interesting aspect of social odometry is that it naturally leads to the emergence of collective decisions within the swarm (Gutiérrez et al., 2010). Indeed, when there are multiple goal areas to localize (*e.g.*, multiple resources to

exploit), by sharing the available information the robots not only improve the accuracy of their localization but can also decide which area to target. The sum of individual decisions leads to a self-organized behaviour that makes the swarm choose between focusing on a single area/resource or exploiting in parallel several ones.

The efficiency of social odometry as a navigation mechanism and the resulting collective dynamics of decision making depend heavily on the way information is shared and aggregated in the robot swarm. In particular, we found that even small variations in some parameters of the individual behaviour may lead to huge differences in the swarm dynamics. For this reason, in this paper we propose three new parameter-free mechanisms for information aggregation and processing, and study them to ascertain their properties in terms of (i) the efficiency in supporting the swarm navigation and (ii) the ability to produce a collective decision when multiple goal locations are present. The results we obtain allow us to understand the properties of the collective behaviours generated by each information processing mechanism. On the basis of such knowledge and depending on the specific needs of the application at hand, a principled choice of the most appropriate mechanism can be made.

## State of the Art

**Navigation in Swarm Robotics** There are various ways to improve navigation through information-sharing within a swarm. Ducatelle et al. (2011) model a swarm as a communication network that propagates relevant information. Each robot in the swarm maintains a table with navigation information about all known robots, similar to how nodes in a mobile ad hoc network maintain routing tables. Then, the robots propagate the available information and use the table to find the best path to reach a target robot within the swarm. Sperati et al. (2011) also study navigation in a swarm robotics context. In this case, communication is performed through visual signals only and therefore the information exchanged is much less structured. For this reason, they used artificial evolution to synthesize effective navigation strategies.

Several studies in swarm robotics implement navigation and exploration algorithms without sharing structured information, sometimes exploiting robots as physical landmarks. Rekleitis et al. (2001) divided the swarm in two teams, one moving and the other stationary, serving as a reference for navigation. The teams alternate between stationary and moving states. Nouyan et al. (2009) exploit robots to form complex structures such as chains, in which one end of the chain connects to a central place while the other end explores the environment. Once the goal location is reached, the chain can be exploited by other robots for navigation purposes, or a bucket brigade method can be used for transporting objects along the chain (Ostergaard et al., 2001).

**Collective Decisions** When there are several goal/resource locations present in the environment, the robots may make a collective decision and focus on the exploitation of a single one. This can be beneficial if it is necessary to aggregate a sufficient number of robots in support of the collective localization, or if exploitation requires several robots at the resource. However, this may lead to congestion (*i.e.*, the path to the resource is overused and robots have trouble navigating) or overexploitation of the resource. In this case, the swarm is better off exploiting several resources in parallel.

In order to agree on one option, the robots can either switch to the best option available in their neighbourhood, or average out all the available information. Social odometry allows doing both simply by tuning a single parameter (Gutiérrez et al., 2010). Olfati-Saber et al. (2007) study the swarm as a multi-agent network and present a theoretical framework for the analysis of consensus algorithms. It is possible to obtain collective decisions also through the amplification of the various opinions present in the swarm. Following this approach, the more an opinion is represented in the swarm, the higher the probability of robots switching their opinion (Garnier et al., 2007, 2009; Montes de Oca et al., 2011). This approach requires gathering the opinion of several neighbours, while social odometry works with peer-to-peer interactions, which is easier to implement.

## Social Odometry & Information Processing

In our experiments, the goal of the robots is to locate both a home area and a goal area and then to efficiently navigate back and forth between them. Once one of these two target areas is discovered, its position is kept in memory and updated using odometry. The information about target areas is shared with other robots upon encounter, following the social odometry mechanism. Within this framework, we study the navigation process, the social dynamics, and the link between the two. In the following, we first describe how robot use the available information (either from individual or social odometry) for navigation purposes. Then, we introduce the information processing mechanisms we have devised.

## The Controller

The behaviour of the robot is defined by a finite state automaton with five states: *Explore*, *Go Home*, *Go to Goal*, *Leave Home*, *Leave Goal* (Fig. 1). Robots start in the *Explore* state and return to it whenever they lack relevant information. The other four states form a loop that corresponds to the robot navigating back and forth between the target areas: go to a target area, enter and leave it, then go to the next one. On top of these control states, both short and long range collision avoidance is implemented.

The robots start without any prior knowledge about the location of the target areas. Therefore, they first have to explore the arena. When in the *Explore* state, the robots perform a random walk until they discover the position of

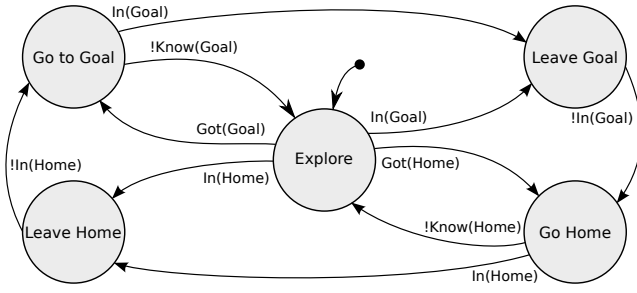

Figure 1: Robot's finite-state automaton. The circles define the states while the arrows define the transitions.  $In(Area)$ ,  $Area \in \{Home, Goal\}$ , is true when a robot senses the grey level of the area,  $Know(Area)$  is true when the robot knows the position of the area,  $Got(Area)$  is true when it just gets this estimation. The robots start in the *Explore* state.

both target areas (home and goal). This can happen in two ways: either they receive relevant information from teammates or they stumble upon a target location ( $Got(Area)$  becomes true, with  $Area \in \{Home, Goal\}$ ). In both the *Go to Goal* and *Go Home* states, the robots move straight to the target location, possibly avoiding other robots and obstacles. Along their travel, they update the target areas location using odometry and update their confidence in the information. The confidence is defined as the inverse of the distance that the robot had travelled from the target area. Therefore, a straight path results in a higher confidence than a curved one.

Once a robot reaches an area (*i.e.*,  $In(Area)$  is true), it traverses it in a straight line (possibly dodging other robots to avoid collisions) and stores the area location. In order to get an estimated position closer to the center of the area, the robot averages its entering and its exiting positions. No matter how many goals there are in the arena, the robots always memorize only one home and one goal (the last seen or agreed upon).

### Information Sharing and Processing

While robots navigate between target areas, they share the information they have on relative locations in order to counterbalance the decrease in information confidence. Not all information is shared at the same time. When in the *Explore* state the robots share the sole information they have. In the other states, the robots share only the information of the last visited location. The information received by a robot is aggregated with the robot's own information. The way this aggregation is performed depends on the information processing mechanism implemented. Given that robots do not share the same reference frame, a transformation is needed. This is made possible by knowing the relative position (range and bearing) of the robot that is sharing its information (for more details, see Gutiérrez et al., 2009). Once the location is obtained in a shared reference frame, the information aggrega-

tion process takes place. Here, we first describe the information aggregation mechanism used by Gutiérrez et al. (2009), and then we introduce our contributed mechanisms.

Let  $i$  and  $j$  be two robots,  $i$  receiving a message from  $j$ . Let  $\mathbf{p}_i$ ,  $\mathbf{p}_j$  be their estimated position of an area (either home or goal) and  $c_i$ ,  $c_j$  the confidence over their respective estimation. The result of any aggregation is the updated couple  $\langle \mathbf{p}_i, c_i \rangle$ . The aggregation mechanism used by Gutiérrez et al. (2009) is based on a Fermi distribution. A weight is calculated from the difference in confidence in order to make a linear combination of the positions:

$$\langle \mathbf{p}_i, c_i \rangle \leftarrow k \cdot \langle \mathbf{p}_i, c_i \rangle + (1 - k) \cdot \langle \mathbf{p}_j, c_j \rangle$$

$$k = \frac{1}{1 + e^{-\beta(c_i - c_j)}}$$

The parameter  $\beta$  measures the importance of the relative confidence levels in the information aggregation. For low values, the aggregation is close to an average, ignoring the confidence. For higher values, the aggregation is stiff: only the information with highest confidence is kept. Finding the right value of  $\beta$  is often a process of trial and error. Our contribution in this paper is the introduction of three parameter-free aggregation mechanisms: *Hard Switch (HS)*, *Random Switch (RS)* and *Weighted Average (WA)*.

**Hard Switch (HS)** In this winner-take-all mechanism, the robots keep the information with highest confidence (either the current information or the received one) and discard the other one. This mimics the Fermi mechanism with a high  $\beta$ .

$$\langle \mathbf{p}_i, c_i \rangle \leftarrow \langle \mathbf{p}_x, c_x \rangle, \quad x = \arg \max_{k \in \{i, j\}} c_k$$

**Random Switch (RS)** As in the mechanism above, here the robots keep one piece of information and discard the other. In this case, however, the switch is stochastic: the higher the confidence, the higher the probability of accepting the information. In practice, this mechanism is a stochastic version of the *HS*.

$$P(\langle \mathbf{p}_i, c_i \rangle \leftarrow \langle \mathbf{p}_j, c_j \rangle) = \frac{c_j}{c_i + c_j}$$

**Weighted Average (WA)** This mechanism consists in a linear combination of both estimated positions with their confidence as weight. On the one hand this implies no loss of information, on the other hand, when information about different goals is aggregated, the new position may not coincide with a real goal location, leading to the apparition of artefacts. While the Fermi mechanism focuses on the difference between the two confidences, here we directly use each of them as weights.

$$\langle \mathbf{p}_i, c_i \rangle \leftarrow \left\langle \frac{c_i \cdot \mathbf{p}_i + c_j \cdot \mathbf{p}_j}{c_i + c_j}, \frac{c_i + c_j}{2} \right\rangle$$

Figure 2: Setup of the experimental arena. The home area is placed in the center of a circular arena of 11 m radius surrounded by walls (not displayed). The goals are characterised by their distance to the home  $d_i, d_j$  and the angles they form with each other  $\alpha_{ij}$ .

## Experiments

We used an experimental setup with as few variables as possible: a circular arena (radius: 11 m) with the home in the center and the goals scattered around (Fig. 2, surrounding walls not shown). The goals are defined by their distance to the home ( $d_i$ ) and the angle between each other ( $\alpha_{ij} \in [\pi/3, \pi]$ ). Both goal and home are of radius 50 cm, and are differently coloured in grey levels to be distinguished by the robots.

Our experiments are performed in the ARGoS open source multi-robot simulator (Pinciroli et al., 2012). The robots we use are the marXbots (Bonani et al., 2010). To accomplish their task, the robots are equipped with several sensorimotor and communication devices. In our experiments, the robots use the infrared ground sensors to check whether they entered an area and to detect its type (home or goal) depending on the area’s grey level. They also use the infrared proximity sensors for short range collision avoidance and the range&bearing device for both communication and long range collision avoidance among robots (Bonani et al., 2010). This last device gives both angle and distance between neighbouring robots and allows them to send short messages. Wheels encoders provide the movement vector for odometry. A simulated gaussian noise with 5% standard deviation models the odometry estimation error. The control loop is executed 10 times per second. Unless stated otherwise, we used 75 robots spawned randomly.

By varying the number of goals, we study different aspects of the collective behaviour, such as the impact of the density of robots on their navigation abilities, the collective decision made by the swarm in a two goals setup, and how this generalizes in multiple goals setups. In the following, we briefly describe the experiments we present in this paper.

**Single Goal** When a single goal is present, we expect that all robots will converge on the same path. The more robots in the arena, the harder it is for them to avoid each other. As density rises, the robots have to handle more and more congestion on their path, which leads them to travel bigger distances and to accumulate more error. This also corresponds to less round trips between home and goal, hence lowering

the efficiency of the swarm. We define the density on a path as the number of robots on it divided by its length.

In order to study the impact of density on navigation, we devised an experimental setup in which we vary both the distance between the home and the goal and the number of robots. All three information processing mechanisms are tested and compared with a benchmark condition in which the robots are provided with perfect information (*PI*) about the goal and home locations. In each experiment, we measure the navigation speed, computed as the number of round trips over time and we study its evolution for values of density between 2 and 40 robots/m. For each density value, we run 100 trials in which we randomly draw the distance between home and goal in the interval [3,8] m, and we compute the corresponding number of robots to obtain the specified density value (which will be in the range [6,320]).

**Two Goals** When there is more than one goal, a decision has to be made as how to spread the robots among the available paths. In this setup, we study if and how the robots converge on one path as well as the implications of such convergence over efficiency. In order to study this decision making process, we count the number of robots committed to each goal, as well as the uncommitted ones. Given that robots do not distinguish between different goals and only store one estimated position  $\mathbf{p}_g$ , a robot is considered to be committed to a goal  $i$  among  $n$  possible if it has information about both goal ( $c_g \neq 0$ ) and home ( $c_h \neq 0$ ), and if goal  $i$  is the closest one to the robot’s estimated goal position  $\mathbf{p}_g$ .

In this setup, we have two goals which can be either at short distance (5 m) or at long distance (8 m). We run experiments with both equal and different distances for the goals: Short/Short (*SS*), Short/Long (*SL*) and Long/Long (*LL*). For each condition, we perform 1000 replications by randomly varying the angle between the sources with  $\alpha_{ij} \in [\pi/3, \pi]$  (cf. Fig. 2).

**Multiple Goals** The environment in which a swarm evolves is rarely as simple as in the two goals setup. Through a multiple goals setup, we enquire about the scalability of the results previously gathered.  $M$  goals are uniformly distributed around the home location, with an angular separation between adjacent goals of  $\pi/M$ , where  $M \in [3, 6]$ . To investigate both the navigation and the decision making abilities, we test three different conditions. Either all goals are at the same distance, short (*SSS*) or long (*LLL*), or a single goal is closer to home (*SLL*). For each condition, we performed 250 trials.

## Results

Each trial in all the previous setups lasts 20 minutes of simulated time. We use the same random initialization in all the runs for the different opinion processing. For each run

Figure 3: Impact of density on navigation efficiency for each mechanism and in the perfect information control condition. Each line is the mean over 100 trials.

we compute the number of robots on each path to study the dynamics of collective decisions, and the number of round trips to study the navigation efficiency.

### Navigation

As we can see in Fig. 3, all the proposed mechanisms and the control condition with perfect information (*PI*) follow the same tendency. For low densities, we can observe a linear increase in the number of round trips. With higher densities, the growth slows down. As expected, robots with perfect information are the most efficient at first, but their efficiency reaches a peak because of the artefacts created by perfect information. With *PI*, since all robots aim at the center of the target areas (either home or goal), as the density rises they have increased difficulties in avoiding collisions and in entering or exiting the target areas.

Congestion has a lower impact on navigation efficiency with social odometry. In this case, *WA* proves to be more resilient to congestion than *HS* and *RS*. This is due to a smoother navigation in the surrounding of the home and goals, where robots try to enter small and densely populated area. First, since the *WA* mechanism never discards information but averages it, the precision on the estimated position is better than with *HS* or *RS*. Second, the reception of even a slightly better information is smoothly integrated in the *WA* mechanisms, while in both *HS* and *RS* it may cause a large leap of the new location, which may be difficult to reach in case of high densities.

### Collective Decision

Congestion explains why sometimes it is better to spread along multiple paths when there is more than one goal/resource. This decisions impacts not only the efficiency but also the spatial arrangement of the swarm and the way it reacts to changes in the environment.

**Decision** The decision pattern of the swarm results from the sum of local decisions made by the robots. The dynam-

ics of the collective decision are shown in Fig. 4, which plots the convergence pattern generated by the *HS* mechanism when confronted with the *SL* experimental condition. Here the swarm decides to focus on the closest area/resource and most robots converge quickly on the associated path. This behaviour is typical of all three social mechanisms when there is a goal closer to home. We can observe three different phases. At first (0-120 s), most robots are uncommitted and explore for goal areas, reinforcing each as they discover them. Then (120-400 s), a competition among the two alternative paths occurs. The shorter path is reinforced more because of the better information the robots have when encountering robots coming from the other goal. Eventually, the swarm enters a maximization state in which mostly one path is exploited while uncommitted robots continue to join.

Fig. 5 left shows the percentage of robots that choose path A (*i.e.*, the shortest path in the *SL* condition). We note that in the *SL* case, all information aggregation mechanisms lead to convergence on a single path with at least 90% of the robots. Both *HS* and *RS* always lead to a convergence on the closest goal. Similarly for *WA*, which however presents also a low probability to make the robots converge on the distant goal. This happens because with *WA* no information is discarded. When a large number of robots discovers the distant goal early in the experiment, they may influence the whole swarm despite the lower confidence in their information. This cannot happen in the *HS* and *RS*, because low quality information is instantly discarded. In both the *SS* and *LL* experimental conditions, when there is no better choice, *HS* and *RS* lead to a split in the swarm, and robots spread among the two paths (Fig. 5 left). In these experimental conditions, the more robots on a path, the higher the congestion, and the larger the distance the robots travel. This causes robots to have worse confidence in their information with respect to those from a less congested path. Therefore, switches to the other path are very likely. Congestion cre-

Figure 4: Evolution of the robots repartition between the two target areas using *Hard Switch* in the Short/Long condition. Bold lines indicate the mean over 1000 repetitions, and the shaded areas indicate the standard deviation.

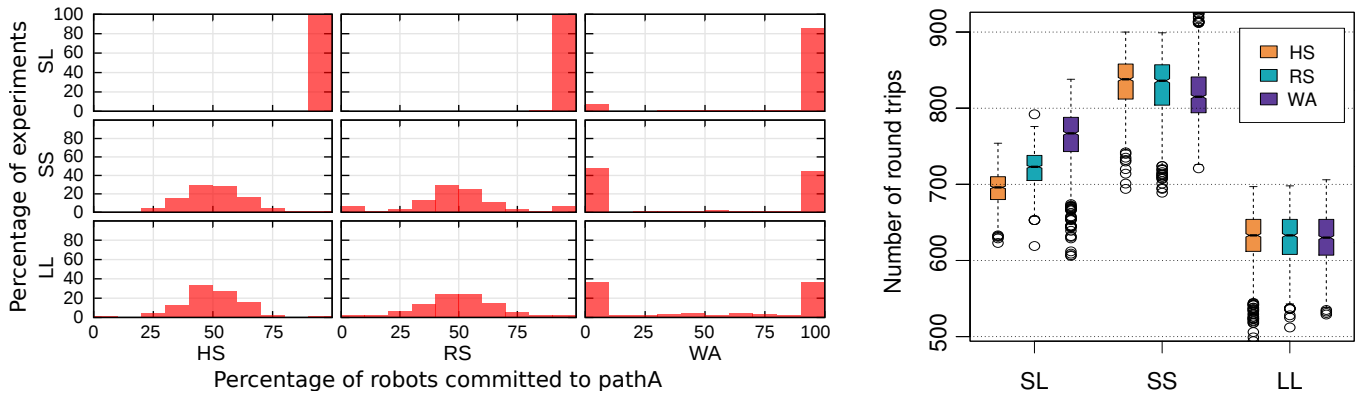

Figure 5: Left: robots repartition on path A. Each histogram shows the observed frequencies of the number of robots committed to path A (the shortest possible path). Right: efficiency of the swarm for two goals, for all mechanisms and conditions. Each box represents the inter-quartile range, whiskers extend to 1.5 times the corresponding quartiles, and dots represent outliers.

ates a sort of negative feedback that leads to an oscillating dynamics in which no decision ends up being taken. On the contrary, WA is not affected by such negative feedback and systematically leads to convergence (randomly on either path, the setup being symmetrical). Indeed, the worse confidence resulting from congestion is counterbalanced by the larger number of robots with which the information is shared and averaged. Therefore, the swarm converges to the more populated path.

**Efficiency** The robot behaviour does not explicitly encode the ability to make collective decisions. Instead, it is conceived to provide efficient navigation ability thanks to the information shared within the swarm. The decision process is an emergent result of this behaviour and so is the variation in efficiency depending on the setup and the mechanisms involved, as shown in Fig. 5 right. In the SL condition, all three mechanisms make the robots converge on the closest path, therefore resulting in density of 15 robots/m. As shown in Fig. 3, WA is more resilient to congestion, and this is why it is the most efficient mechanism in this setup, followed by RS and HS. In the SS condition, both HS and RS result in the swarm splitting between the two paths as discussed above. By exploiting two paths with a low density of 7.5 robots/m (instead of one with high density of 15 robots/m) the robots create less congestion, which explains why the performance for HS and RS is slightly better than in the WA case. Indeed, WA makes the swarm converge on a single path with high density, and navigation is slightly less efficient. Congestion has a lower impact in the LL conditions as both densities (9.4 robots/m on a single path, 4.7 robots/m on two paths) fall in the linear part of the congestion curve (see Fig. 3), explaining why the mechanisms result in the same efficiency.

### Generalization to Multiple Goals

The dynamics we observe with multiple goal locations are similar to the ones displayed in the two goals setup, no mat-

ter the number of added goals. Fig. 6 shows the percentage of robots that choose path A (*i.e.*, the shortest path in the SLL condition), when multiple goal locations are present. All mechanisms leads to convergence in the SLL case, even if WA sometimes leads to the selection of one of the distant goals, for the same reasons discussed in the two goals setup. We can observe a similar splitting behaviour in the SSS and LLL conditions for both HS and RS, while convergence is observed for WA. When the swarm splits, the repartition of robots is not anymore centred on 50% but closer to 33%, meaning that the repartition is not anymore among only two paths. Nonetheless, not all are exploited at the same time, as can be inferred from the existence of paths selected by no robot. This can be explained by the oscillation dynamics discussed earlier. When the amplitude of the oscillations is greater than the number of robots on a path, all the robots on this path switch to another one. This happens in the case of multiple goals because robots are spread among more paths and therefore their number on each is lower.

To better understand the exploitation of the available resources/goals, in Tab. 1 we report the average percentage of robots on the different paths, ordered from the most to the least exploited path. We note that the number of exploited goal locations is most of the time no more than 3. This explains why the efficiency of the swarm does not vary with the number of available resources, as shown in Fig. 7. The slight increase in performance can be attributed to the fact that the more goals there are, the easier it is for uncommitted robots to join a path earlier in the experiment. Overall, we note similar patterns over efficiency between the multiple goals condition and the two goals condition.

When there are multiple goals, WA in the SLL condition leads to a frequent selection of a distant goal instead of the closest one, as shown in Fig. 6. If several distant locations are present, they end up reinforcing each other as their angular distance becomes smaller. In other words, two distant goal locations that are close to each other attract more robots

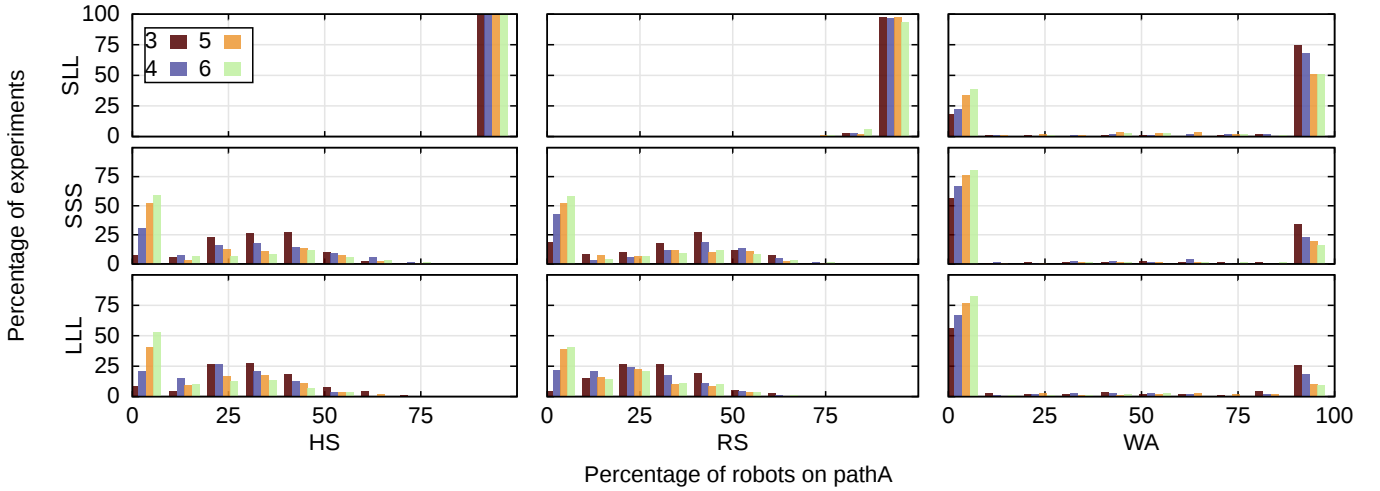

Figure 6: Robots repartition on path A for different number of goal areas (3,4, 5 and 6). Each histogram shows the observed frequencies of the number of robots committed to path A (the shortest possible path).

Table 1: Repartition in percentage of robots for 3, 4, 5 and 6 goals. The 1<sup>st</sup> goal is the one associated with the highest number of robots. The mean and maximum of the standard deviation is (4.7, 10.5) for *HS* and *RS* and (6.1, 16.9) for *WA*.

than a single closer location. This explains why the chance of *WA* leading to the selection of a distant goal increases with the number of goals.

## Discussion

The experiments above reveal the specificities of the three information aggregation mechanisms. *WA* leads to convergence to a single path in all conditions, but this is slower and error-prone. In the whole, *WA* leads to better cohesion of the

swarm and deals better with congestion thanks to more accurate information about the target areas. *HS* and *RS* also lead to convergence when there is a shorter path to exploit, and handle better the presence of multiple distant goal locations. When congestion results in inefficient navigation, both mechanisms lead to the exploitation of multiple paths, spreading the load of robots in a balanced way with similar dynamics, although *HS* appears to be stiffer than *RS*.

## Conclusions

In this paper, we presented an extensive analysis of three parameter-free information processing mechanisms for social odometry. We studied the impact of these mechanisms on the navigation efficiency and on the dynamics of the swarm. In particular, we observed how the information processing mechanism can either lead to convergence on the exploitation of a single path, or to splitting over multiple comparable options. These results are meant to give future designer a guideline of which mechanism to choose depending on the situation at hand.

In future work, we plan to further investigate the dynamics of social odometry in order to provide an optimal load-balancing behaviour. This would maximize the exploitation of different resources and provide the swarm the ability to react to changes in its environment in real time. Additionally, we will experiment with more complex paths, for instance in the presence of obstacles. Also, physical objects to be retrieved may be placed within the goal areas in order to simulate a more realistic environment and making it possible to test the collective behaviour with real robots. Last, heterogeneity can be added in the swarm. On the one hand, individual robots may get committed to a goal with different individual preferences, leading to a better exploration of the environment. On the other hand, different groups of robots

Figure 7: Efficiency of the swarm for multiple goals and all mechanisms and conditions. See Fig. 5 for more details.

could compete for the best source, each of them having different information aggregation mechanisms, leading to a different exploitation of resources among different groups.

## Abstract

Michigan-style learning classifier systems have availed themselves as a promising modeling and data mining strategy for bioinformaticists seeking to connect predictive variables with disease phenotypes. The resulting ‘model’ learned by these algorithms is comprised of an entire population of rules, some of which will inevitably be redundant or poor predictors. Rule compaction is a post-processing strategy for consolidating this rule population with the goal of improving interpretation and knowledge discovery. However, existing rule compaction strategies tend to reduce overall rule population performance along with population size, especially in the context of noisy problem domains such as bioinformatics. In the present study we introduce and evaluate two new rule compaction strategies (QRC, PDRC) and a simple rule filtering method (QRF), and compare them to three existing methodologies. These new strategies are tuned to fit with a global approach to knowledge discovery in which less emphasis is placed on minimizing rule population size (to facilitate manual rule inspection) and more is placed on preserving performance. This work identified the strengths and weaknesses of each approach, suggesting PDRC to be the most balanced approach trading a minimal loss in testing accuracy for significant gains or consistency in all other performance statistics.

## Introduction

Learning classifier systems (LCSs) are an adaptive rule-based class of algorithms which combine evolutionary computing with machine learning and other heuristics (Holland, 1986; Wilson, 1995). More recently, Michigan-style LCSs (M-LCSs) have been shown to be an effective approach for the detection and characterization of complex patterns of association in epidemiological data mining. This work applied M-LCSs to identify patterns of multi-locus interaction (i.e. epistasis) as well as heterogeneity when seeking to connect predictive genetic and environmental variables with human disease phenotypes (Urbanowicz and Moore, 2010; Urbanowicz et al., 2012b, 2013). LCSs yield a resulting model/solution, comprised of an entire population of rules, affording them the ability to learn iteratively and distribute learned patterns across this population. These characteristics make the application of LCSs to the problem of heterogeneous patterns particularly appealing.

A notable effect of this iterative, “one instance at a time”, LCS learning is the transitional nature of the rule population, i.e. the rule population is constantly changing with offspring rules continually being added and rules of lesser fitness being eliminated. At any given learning iteration, an unknown number of rules are bound to exist in the rule population that make little or no contribution to the overall performance of the system. These include (1) rules that overlap in describing the problem space, (2) poor, recently generated rules, that the algorithm has yet to identify as poor (i.e. low accuracy), and (3) conflicting rules that harm overall performance. Additionally, a solution comprised of a population of many rules can make interpretation and knowledge discovery a considerable challenge. Interpretation of an LCS rule population had been traditionally approached with manual rule inspection, i.e. an expert would examine the best rules of a population in an attempt to extract knowledge. With this task in mind, a *rule compaction* strategy that could consolidate the rule population to a minimum set of critical, human readable rules was considered to be useful.

Wilson implemented the first LCS rule compaction strategy applied to his XCSI algorithm. This Compact Rule-set Algorithm (CRA) achieved a much smaller ruleset, yet maintained high training and testing performance when applied to Wisconsin Breast Cancer dataset (Wilson, 2002). Like most strategies that would follow, rule compaction was run following completion of the LCS algorithm as a form of post processing. Wilson’s approach was designed for classifiers that had been highly trained such that the rules were maximally general and always correct in their classification of the test data. CRA was implemented purely to facilitate manual rule inspection by dramatically reducing the rule population size. Later, Fu and Davis revised CRA in order to handle less well trained, noisy classifier systems (Fu and Davis, 2002). The consideration of noisy problems wherein training and testing accuracies might never approach 100% accuracy is critical in problem domains such as bioinformatics and epidemiology. Without doing so, rule compaction is likely to sacrifice performance of the rule population in exchange for minimal size. However, the shortcomings of

CRA and Fu's approaches lie in heavy computation and time complexity, because overall rule population performance needs to be calculated each time a classifier is considered for addition or removal. In an effort to speed up rule compaction, Dixon *et al.* developed CRA2 which focused both on speed and minimal rule population size (Dixon et al., 2003). CRA2 yielded similar performance to CRA but ran much faster when tested on the same dataset. Other similarly themed LCS rule compaction strategies include an approach for continuous-valued problem spaces (Wyatt et al., 2004), an approach for online rule compaction (Gao et al., 2006), an approach for clustering in XCS (Tamee et al., 2007), an approach which adds entropy calculation (Kharbat et al., 2008), and an approach designed for fuzzy rule representations (Shoeleh et al., 2011).

Recent efforts to move away from manual rule inspection and instead adopt a global pattern approach to knowledge discovery in LCSs have also shifted the priorities of rule compaction. In the context of complex noisy problem domains, it becomes impractical to expect rules to achieve a balance of maximum accuracy and generality. Therefore, placing too much emphasis on reducing the size of the rule population can lead to a loss of rule diversity and result in a reduction in overall performance. In (Urbanowicz et al., 2012a) a global approach to knowledge discovery is considered which introduced global evaluation statistics, and visualization strategies to achieve knowledge discovery in complex problem domains without manual rule inspection. This work focused on modeling noisy, complex patterns in supervised learning problems. In the present study we explore rule compaction somewhat differently than in previous efforts. First, we focus on LCS algorithms designed to address supervised learning domains. Specifically, while previous compaction strategies were designed to function within the context of XCS (Wilson, 1995), a reinforcement learning based LCS, we examine how rule compaction functions in supervised learning based LCSs such as UCS (Bernadó-Mansilla and Garrell-Guiu, 2003). Second, we approach rule compaction assuming that knowledge discovery will be achieved using a global approach as opposed to manual rule inspection. Lastly, we expand our evaluation of LCS performance beyond run time, training, and testing accuracy to consider the impact of rule compaction on an LCS's power to correctly prioritize predictive attributes and discover complex patterns of association as described in (Urbanowicz et al., 2012a). This expansion evaluates the compacted population's ability to yield successful knowledge discovery, as opposed to just successful classification.

The three rule compaction strategies introduced in this work focus on preserving or increasing the quality of the the final rule population rather than emphasizing a human readable population size. The first strategy, Quick Rule Compaction (QRC), is inspired by the match-covering mechanism in the third stage of CRA (Wilson, 2002). The sec-

ond strategy, Parameter Driven Rule Compaction (PDRC) is largely based on Dixon's approach. Specifically, for each training instance, PCRC finds the classifier in the correct set with the largest product of accuracy, numerosity, and generality and preserves that rule in the final population. The third strategy, Quick Rule Filter (QRF) is more of a rule filter than a compaction algorithm. It simply removes any rule in the population that does not have an accuracy above 0.5. The accuracy of a rule is the frequency of correct prediction for the subset of data instances the rule matches. We compare the resulting rule population performance following that application of our new approaches to three existing approaches (Fu's two approaches and CRA2). Changes in performance statistics are evaluated relative to rule populations without any rule compaction. We consider the advantages and disadvantages of each.

## Methods

In this section we describe (1) the LCS algorithm and run parameters used in this investigation, (2) the six rule compaction strategies considered in this study and (3) the experimental evaluation including data simulation, statistical analysis, and visualization.

### LCS Algorithm

We begin with a brief review of LCS algorithm concepts critical to understanding rule compaction. LCSs make class predictions based on "votes" made by rules which are relevant to a given instance from the dataset. Each rule possesses a condition and a classification. For example consider a hypothetical rule (0#1## - 1). The '#' serves as a wild card. This rule would match an instance from the data that looks like (02100 - 0), but not one that looks like (12100 - 0). Notice that this first instance example matches the rule, but the rule has incorrectly predicted the class to be '1', when in fact the class of this instance is '0'. These matching rules form what is known as a match set (i.e. the subset of rules in the population which match the attribute states of the dataset instance.) All rules that both match the instance as well as make the correct prediction form a correct set. During supervised LCS learning, when a rule is included in both a match and correct set, it's accuracy and fitness will increase, while if it is only involved in a match set (i.e. it matches but makes an incorrect classification) it's accuracy and fitness will decrease. For an in-depth review of LCS algorithms and how they function we refer readers to (Urbanowicz and Moore, 2009).

In order to evaluate each rule compaction strategy within a complex, noisy bioinformatics problem domain, we used an expanded Python encoding of AF-UCS (Urbanowicz et al., 2012b). AF-UCS (attribute feedback UCS), is an expanded and modified implementation of UCS (Bernadó-Mansilla and Garrell-Guiu, 2003) which incorporates a form of memory which feeds back into the genetic algorithm during

learning. UCS, or the sUpervised Classifier System, is an M-LCS based largely on the popular XCS algorithm (Wilson, 1995) but replaced reinforcement learning with supervised learning. UCS was designed specifically to address single-step problems such as classification and data mining, where delayed reward is irrelevant, and showed particular promise when being applied to epistasis and heterogeneity in (Urbanowicz and Moore, 2010). This expanded version of AF-UCS incorporates expert knowledge covering as described in (Urbanowicz et al., 2012c) to speed up learning.

The selection of run parameters for this evaluation was arbitrary. We adopted mostly default M-LCS run parameters. Parameters unique to this study include: 200,000 learning iterations, a rule population size of 2000, a rule generality of 0.75 in covering, tournament selection, uniform crossover, and subsumption on. The implementation described above is available on request ([ryanurbanowicz@gmail.com](mailto:ryanurbanowicz@gmail.com)) and will be posted on the LCS and GBML Central webpage.

### Rule Compaction Algorithms

The first LCS rule compaction strategy was CRA, a 3-stage algorithm aimed at dramatically reducing the number of rules and producing a human-readable ruleset (Wilson, 2002). Separate work modified the strategy for rule sorting in the first two stages of CRA such that less well trained classifiers seeking to model noisy problems could be taken into account (Fu and Davis, 2002). Two related strategies from this work are referred to throughout this paper as Fu1 and Fu2. Due to the inherent noise and complexity of our target problem domain, we have chosen to evaluate the two most successful approaches proposed by Fu and Davis as well as Dixon's CRA2, which yields similar performance but runs much faster (Dixon et al., 2003). These implementations are used as a baseline of comparison for our own proposed rule compaction strategies. In the following subsections we describe each of the six rule compaction algorithms considered, three existing strategies (Fu1, Fu2, and CRA2) as well as our three proposed strategies (QRC, PDRC, and QRF). Each have been implemented within the LCS algorithm described in the previous section, coded in Python.

**Strategy 1: Fu1** Fu's first approach is summarized as:

**Stage1:** Sort the rules by ascending numerosity (i.e. the number of copies of an identical rule). Begin with the first rule in the list, eliminate it and test the performance of the rest rules. If the performance becomes better or unchanged, continue to remove the next rule. If the performance is worse, reinsert that classifier to the ruleset and proceed to stage 2.

**Stage2:** Continue deleting each rule orderly from the ruleset, evaluating the performance of the remaining rules. If the performance is reduced after deletion, move that rule to the new ruleset. The deleted rule is

not considered in the next round of evaluation. After all rules being tested in such way, pass the new ruleset with all the rules causing performance reduction to the next stage.

**Stage3:** Calculate the number of instances in the training set a rule matches, move the rule matching most instances to the final ruleset, and delete instances matched to that rule from training set. Repeat the above three steps until the training dataset is empty or no rules match the remaining instances.

**Strategy 2: Fu2** Fu's second approach preserves the first two stages, while modifying stage 3 to take performance into consideration. The third stage can be described as follows:

**Stage3:** First sort the list of rules obtained from stage 2 by numerosity in increasing order, remove the last rule and evaluate the performance of the remaining classifiers. If the performance drops, reinsert that rule to the top of the list, thus it is involved in the following evaluation. Repeat such test on all classifiers and the final ruleset is composed of classifiers left in the list.

**Strategy 3: CRA2** Dixon's CRA2 approach avoids the need for step-wise performance evaluations. The basic idea of CRA2 is to identify the most useful rule for each instance in the training data. CRA2 examines each instance in the training data and builds a correct set from the rule population. For each instance, the most 'useful' classifier is marked for preservation in the final rule population. Dixon's approach determines the most useful rule to be the one in the correct set with the highest mathematical product of accuracy and numerosity. The original CRA2 was implemented in XCS, a reinforcement learning LCS, in which the correct set is called an action set. In the context of our implementation and evaluations, this is only a semantic difference.

**Strategy 4: Quick Rule Compaction (QRC)** Preliminary observations indicated that the third stage of Fu's first approach was the main cause of performance drop. QRC modifies this stage by using fitness instead of the number of instances a rule matches to retain useful rules. Additionally, QRC completely removes the first two stages utilized in both Fu1 and Fu2, eliminating the need for incremental performance evaluations of the whole rule population. Note that QRC ranks rules by fitness only once at the beginning of rule compaction. This ranking is not updated following the subsequent removal of instances. This differs from the original match-covering mechanism with the intention focusing on globally high fitness and the reduction of run time. Also, it is worth pointing out that in the LCS algorithm used, rule fitness is equal to rule accuracy. Pseudo-code for QRC is given in Algorithm 1.

```

Sort the rules decreasingly by fitness (or accuracy);
while Training dataset is not empty do
    MatchCount = 0;
    for Each instance in the training dataset do
        Determine whether it matches the first rule;
        if It matches then
            MatchCount ++;
        else
            Move the instance to new training set;
        end
    end
    if MatchCount > 0 then
        Copy the first rule to the final set;
    end
    Update training set to new training set;
    Delete the first rule from the sorted ruleset;
end

```

**Algorithm 1:** Quick Rule Compaction

#### Strategy 5: Parameter Driven Rule Compaction (PDRC)

Our PDRC approach is quite similar to Dixon’s speedy CRA2 implementation. In preliminary work we explored three different rule parameters (accuracy, numerosity, and generality) in an attempt to find the best numerical way to capture the utility of a rule. We considered them separately, the product of pairs, and the product of all three together. Keeping in mind that CRA2 utilized the product of accuracy and numerosity, we found that the product of accuracy, numerosity and generality performed best. Pseudo-code for PDRC is given in Algorithm 2.

```

for Each instance in the training dataset do
    Create MatchSet;
    Create CorrectSet;
    Find the classifier with highest product of accuracy,
    numerosity and generality in the CorrectSet;
    if The classifier is in final set then
        Pass;
    else
        Add the classifier to the final set;
    end
end

```

**Algorithm 2:** Parameter Driven Rule Compaction

**Strategy 6: Quick Rule Filter (QRF)** Our last proposed approach (QRF) is simply a filter which scans the rule population and deletes any rule with an accuracy  $\leq 0.5$ . This is intended to remove rules that predict class no better than by random chance at the time when learning was halted. Additionally, a rule is also deleted if it covers (i.e. matches) less than two instances in the dataset. This removes rules that are likely to be blatantly overfitting training instances. However,

such a deletion is prevented if the rule in question specifies only a single attribute. This accounts for the possibility of a rare variant, (i.e. a rare attribute state), which may be useful to preserve when seeking to interpret the rule population.

## Experimental Evaluation

**Data Simulation** Consistent with the nature of our target noisy bioinformatics problem of interest, we have applied our LCS algorithm in conjunction with all rule compaction strategies to a large set of simulated datasets which concurrently model heterogeneity and epistasis as they might appear in a SNP gene association study of common complex disease Urbanowicz and Moore (2010); Urbanowicz et al. (2012b,c). All data sets were generated using a pair of distinct, two-locus epistatic interaction models, both utilized to generate instances (i.e. case and control individuals) within a respective subset of each final data set. Each two-locus epistatic model was simulated without Mendelian/main effects, as a penetrance table as in Urbanowicz and Moore (2010). Due to the computational demands of LCSs, this study limited its evaluation to 3 heterogeneity/epistasis model combinations. For simplicity the minor allele frequency of each predictive attribute was set to 0.2, a reasonable assumption for a common complex disease SNP. The three model combinations included a pair of models with a heritability of either (0.1, 0.2, or 0.4). We considered model architectural “difficulties” of both “easy” and “hard” Urbanowicz et al. (2012d). Balanced datasets simulated from these models were generated as having four different sample sizes (200, 400, 800, or 1600) and a heterogeneous mix ratio of either (50:50 or 75:25) (e.g. 75% of instances were generated from one epistatic model, and 25% were generated from a different one). Twenty replicates of each dataset were analyzed and 10-fold cross validation (CV) was employed to measure average testing accuracy and account for over-fitting. Together, a total of 48 data set configurations (3 Model Combos x 4 Sample Sizes x 2 Ratios x 2 Difficulties), and a total of 960 data sets (20 random seeds each) were simulated. With 10-fold CV, 9600 runs the AF-UCS-based algorithm were completed followed by the same number of runs for each of the six compaction strategies.

**Statistical Analysis** For each run we track training accuracy, test accuracy, rule generality, macro population size, micro population size, and the run time required for rule compaction. Unlike previous investigations of rule compaction, we also consider three power estimates: (1) the power to find both heterogeneous underlying models, (2) the power to find at least one underlying model, (3) and the power to correctly rank attribute co-occurrence (Urbanowicz et al., 2012a). Power indicates the user’s ability to reliably mine knowledge from the evolved rule population. Co-occurrence power is a reflection of our ability to distinguish heterogeneous models from epistatic interactions. Results

over 10-fold CV are averaged. Statistical comparisons were made using the Wilcoxon signed-rank tests due to a lack of normality in the value distributions. All statistical evaluations were completed using R. Comparisons were considered to be significant at  $p$ -value  $\leq 0.05$ .

In order to further characterize differences between rule compaction approaches, we examine which specific rules remain following compaction. This similarity score is calculated as the ratio of rules preserved in two compacted rule sets to the size of the smaller rule set. Similarity scores were averaged over 10 CV runs.

**Visualization** Part of the global knowledge discovery process includes the application of intuitive visualizations to identify patterns of association within the rule population. In the present study we generate heat-maps to visualize compacted rule populations as described in (Urbanowicz et al., 2012a). Rules are encoded such that any specified attribute is coded as a 1 and any generalized attribute (#) is coded as a 0. Rule populations are visualized as a micro population, which means there are  $N$  copies of each rule reflecting respective numerosity ( $N$ ). The last processing step before visualization involves the application of a clustering algorithm to the encoded and numerosity expanded population of rules. In this study we employed agglomerative hierarchical clustering based on pearson correlation. For rules or attributes having undefined pearson correlation due to uniform values, 0 is assigned for the purpose of visualization. Both clustering and 2D heat-map visualization are implemented in R using *hclut* and *gplots* packages respectively. In this paper, we generate example visualizations using arbitrarily chosen datasets with a sample size of 1600, minor allele frequencies 0.2, model heritabilities of 0.2, a “Hard” model difficulty, and a heterogeneity ratio of 50:50.

## Results and Discussions

Table 1 gives a summary of the metrics evaluating rule populations following compaction. These are compared to the original rule populations prior to any form of compaction (NONE). Three existing approaches were considered (i.e. Fu1, Fu2, and CRA2) as previously described, as well as three approaches that have been proposed here (i.e. QRC, PDRC, and QRF). The color coding within table 1 makes it simple to quickly identify strategies which suffered significant losses, earned significant gains, or maintained performance relative to the original rule population. In reviewing the results, keep in mind that our proposed QRC strategy was most closely related to Fu’s approaches (Fu and Davis, 2002), and our proposed PDRC strategy was most closely related to CRA2. In this work we are most concerned with preserving or, if possible, improving the performance of a rule population while simultaneously seeking to reduce the overall rule population size.

We begin by discussing some of the more obvious trends. All approaches were successful at significantly reducing both the macro population size (i.e. the number of unique rules in the rule population) and the less interesting micro population size (i.e. the number of rules in the population, taking rule numerosity into account). The two Fu approaches yielded the most dramatic decrease in macro population size, followed by our own PDRC and CRA2. As might be expected, our QRF approach resulted in the deletion of only a handful of rules. Next, with the exception of QRC, all strategies significantly increased average rule population generality (i.e. portion of attributes that were generalized using a wild card within a given rule). This metric alone does not tell us much about performance, but all other metrics being equal, it is desirable to have a rule population that is maximally generalized. Given that within our simulated datasets, 20% of the attributes were predictive, wherein only 10% of attributes are predictive for a given heterogeneous dataset instance, we expect that the ideal rule generality would fall between 0.8 and 0.9. Turning our attention to rule compaction time, both Fu strategies took by far the most time to complete, owing to repeated accuracy evaluations of the rule population as a whole. Both CRA2 and our own PDRC strategy yielded similar, dramatically shorter run times. Our QRC approach further reduced run time by an additional order of magnitude, and lastly our QRF approach reduced run time even further by two additional orders of magnitude. Further statistical comparisons indicated that all differences in population size, generality and run time between all strategy pairs were also significant ( $p$ -value  $< 0.001$ ).

Next we examine the impact of each strategy on rule population accuracy and power. Keep in mind that power is a reflection of the algorithm’s success at prioritizing predictive attributes and patterns for successful knowledge discovery. Fu’s first strategy (Fu1) yielded the most significant dramatic loss in both accuracy and power (an apparent trade off with also generating the smallest rule population by far). Differently, Fu’s second strategy (Fu2) instead yielded significant increases in accuracy, but still resulted in modest, significant performance loss within all three power metrics. Comparing this to our proposed QRC strategy (most closely related to Fu1 and Fu2), we similarly observe a significant increase in accuracy (with a particularly notable increase in testing accuracy). Additionally, QRC results in a less significant and less dramatic loss in “Both-Power” and “Co-occurrence Power” when compared to the Fu’s approaches, as well as a small non-significant increase in “Single Power”. Considering our multiple evaluation objectives, our QRC approach appears to outperform both of Fu’s approaches. Interestingly when examining rule population similarity, only 45.51% of Fu1 and 56.55% of Fu2 unique rules were also found in the QRC rule population. Originally, we expected that the few rules left after running

Table 1: A comparison of population characteristics following rule compaction. Each statistic is averaged over all 960 simulated datasets and compared with populations prior to rule compaction (i.e. NONE) to determine statistical significance using the Wilcoxon signed rank sum test. (\*  $p$ -value  $< 0.05$ , \*\*  $p$ -value  $< 0.001$ ). Statistics in yellow have been significantly improved from NONE, while those in red have been significantly impaired. Time values in yellow are relatively fast, while those in red are comparatively slow. For each statistic, the the top finding across all strategies is given in bold.

Fu’s strategies would mostly be included in the larger QRC rule population. It turned out that half of the rules in Fu’s compacted rulesets did not possess a particularly high fitness relative to rules in the original rule population.

Examining CRA2, we observe a very small but significant reduction in both testing accuracy, and “Single Power”. However, CRA2 notably yielded a relatively large and significant improvement in “BothPower”, while maintaining “Co-occurrence Power”. Overall, CRA2 performance was certainly the best of the three existing strategies examined. Comparing CRA2 to our proposed PDRC strategy (again most closely related), we observe that PDRC also yields a small significant loss in testing accuracy. However, average testing accuracy for PDRC is significantly higher than for CRA2 ( $p$ -value  $< 0.05$ ). PDRC also yields a significant increase in “BothPower”, however it is not as large an improvement as with CRA2. PDRC does not significantly impact either “Single Power” or “Co-occurrence Power”. Overall, PDRC better preserves accuracy while also yielding a smaller average macro rule population than CRA2. Note that which micro population is smaller for PDRC than in CRA2, the opposite is true for micro population size. This indicates that PDRC is preferentially selecting rules with a higher average numerosity than CRA2. When examining rule population similarity, 74.89% of the unique rules commonly exist in both CRA2 and PDRC rule populations. This demonstrates CRA2 and PDRC tend to more frequently preserve the same rules within the rule population. It is different from what we observed comparing Fu’s approaches to QRC.

Lastly we examine the performance of QRF. QRF is the fastest strategy, and the only one which both significantly improves accuracy (although not as much as QRC and PDRC) as well as maintaining “BothPower” and slightly improving “Single Power” and “Co-occurrence Power” (how-

ever this improvement is not significant). The most obvious drawback to QRF is that it has very little effect on population size. However in the context of global knowledge discovery strategies, this may be of little importance.

Clearly there are strengths and weaknesses to each of the proposed approaches. For those interested in manual rule inspection with emphasis on obtaining the smallest rule set possible, it would appear that Fu’s approaches are best. If speed and the predictive ability of the rule population are priorities, the results suggest that QRC achieves the largest improvement in testing accuracy and runs approximately 1000 times faster than Fu’s strategies or approximately 10 times faster than CRA2 or PDRC. If the reader is interested in the most well rounded approach, PDRC yields the smallest rule population next to the Fu’s approaches and preserves or even improves all the metrics except a minor reduction in testing accuracy. Finally, if the reader is interested in the fastest approach that has the added benefit of completely preserving accuracy and power, but also does the least to reduce the size of the rule population, we suggest QRF.

## Visualization Results

Figures 1-3 present heat-maps visualizing rule population prior to rule compaction, following Fu2 compaction, and following PDRC compaction, respectively. Each row represents a rule while each column represents an attribute (X0-X19). Yellow blocks indicate attributes which have been specified within a rule, while blue indicates generalization (i.e. don’t care). Within each illustration, only four attributes were modeled as predictive. One epistatic model includes attributes (X0 and X1) and the second independent model includes attributes (X2 and X3). An accurate representation of this underlying model would yield rules that concurrently specify either attribute pair. Notice in Figure 1 that while there is clearly some noise, two distinct yellow

bands, correctly corresponding to (X0,X1) and (X2,X3), are apparent. Additionally hierarchical clustering most strongly links these individual attribute pairs.

In contrast to this successful interpretation of the underlying simulated patterns, Figure 2 shows the visualization of the same rule population following Fu2 compaction. Note that there are far fewer rules in this population, thus the respective row heights are larger than in Figure 1 since fewer rules are forced into the same figure height. Also, notice that while attributes (X2,X3) still form an obvious yellow band, (X0,X1) are no longer as clustered together as strongly, and the overall correct pattern is lost. The correct interpretation of this visual pattern should correspond with power estimates given in Table 1. An example of an effective compaction attempt which maintains, or perhaps, improves the interpretability of the heatmap is given by Figure 3. This figure shows the visualization of the rule population following application of PDRC to the original rule population. Notice that strong clusters are maintained between (X0,X1) and (X2,X3) attribute pairs, and some of the noise is eliminated when compared to Figure 1. Additionally, keep in mind that there are significantly fewer rules in the population visualized in Figure 3 than in Figure 1. It is worth noting that while not shown here, a similar visualization of the rule population following CRA2, yields a similarly clear illustration of patterns modeled in the dataset as seen in Figure 3.

### Conclusions and Future Work

In this study, we evaluate rule compaction algorithms for learning classifier systems (LCSs) with the goal of preserving or improving performance while reducing the size of rule population and facilitating knowledge discovery. Specifically we are most interested in applying rule compaction to problems domains with complex and noisy patterns. In addition, based on new global strategies for pursuing knowledge discovery within an LCS rule population (Urbanowicz et al., 2012a), we evaluate rule compaction performance by prioritizing global interpretation rather than traditional manual rule inspection. We also seek to avoid the most obvious shortcoming of most compaction strategies, i.e. computational complexity. We have introduced two new rule compaction strategies (QRC and PDRC) along with a rule filtering strategy (QRF), and compared them to three existing rule compaction methodologies (Fu1, Fu2, and CRA2) using a broader set of performance criteria than previously considered in similar studies.

The results highlighted the strengths and weaknesses of each rule compaction strategy in the context of our complex, noisy problem domain. Fu1 and Fu2 took the longest to run, yielding the smallest rule populations at the expense of accuracy and power. These strategies may be best suited to easier problems, or in problems where manual rule inspection is preferred. Our QRC strategy ran about 1000 times faster, achieving the highest testing accuracy, but re-

Figure 1: Rule population before compaction.

Figure 2: Rule population after Fu2 compaction.

Figure 3: Rule population after PDRC compaction.

sulted in some minor losses in power. This strategy may be ideal when a very large dataset is being investigated or when the goal is classification rather than data mining. Overall our PDRC strategy yielded the most well rounded performance, with CRA2 close behind. Therefore, out of the six strategies examined, PDRC would be the best choice if a researcher wishes to effectively reduce the rule population size while preserving the overall performance of the rule population. Lastly QRF was the only approach that completely preserved or improved accuracy and power. This approach was also approximately 100000 times faster than Fu's approaches. However, this strategy did little to reduce the overall population size. This strategy would be best for situations in which rule population size is not a concern, but preservation of population performance is critical.

Future work will focus on exploring the constitution of rule sets after applying different rule compaction algorithms. Since there are distinct similarities between the compaction strategies, it would be interesting to further investigate the overlapping rules between populations formed by different strategies and better characterize the makings of an essential classifier. Also, while we have utilized a single specific supervised LCS, we would expect that other LCS implementations would similarly benefit from these proposed compaction strategies, as well as global strategies for knowledge discovery. We expect to utilize these compaction strategies in various real-world analyses and LCSs in future work.

# Empowerment and State-dependent Noise - An Intrinsic Motivation for Avoiding Unpredictable Agents

Christoph Salge<sup>1</sup>, Cornelius Glackin<sup>1</sup> and Daniel Polani<sup>1</sup>

<sup>1</sup>University of Hertfordshire, College Lane, Hatfield AL10 9AB, UK

## Abstract

*Empowerment* is a recently introduced intrinsic motivation algorithm based on the embodiment of an agent and the dynamics of the world the agent is situated in. Computed as the channel capacity from an agent's actuators to an agent's sensors, it offers a quantitative measure of how much an agent is in control of the world it can perceive. In this paper, we expand the approximation of empowerment as a Gaussian linear channel to compute empowerment based on the covariance matrix between actuators and sensors, incorporating state-dependent noise. This allows for the first time the study of continuous systems with several agents. We found that if the behaviour of another agent cannot be predicted accurately, then interacting with that agent will decrease the empowerment of the original agent. This leads to behaviour realizing collision avoidance with other agents, purely from maximising an agent's empowerment.

## Introduction

One important and unique aspect of living organisms is how they generate their behaviour. Sims (1994) demonstrated that simple motivations can be enough to generate complex behaviour that evokes a resemblance of life. Ultimately all organisms are subject to evolution and their behaviour is a product or by-product of a process directed by reproductive fitness and survival. However, from a cognitive perspective, it seems difficult for an agent to always relate behaviour back to survival. From an evolutionary perspective, it is also questionable how the sparse sampling of random behaviours could lead to good solutions. Nature solves this problem with the development of behavioural proxies or motivations (Scott-Phillips et al., 2011), such as the ability to perceive and avoid pain, which produces behaviour considered beneficial for survival. In artificial life the corresponding research aims to identify, quantify and replicate these motivations.

Significant research interest has been directed at methods known as "intrinsic motivations", methodologies to generate behaviours for agents without the requirement of an externally specified reward or utility structure; importantly, they emerge exclusively from the agent-environment dynamics. Here, instead of a specific goal, the generation of behaviour

depends on an internal motivation. Most of them focus on learning and exploration, and try to quantify an organism's urge to understand its environment (Schmidhuber, 1991; Der et al., 1999; Steels, 2004; Prokopenko et al., 2006; Ay et al., 2008).

In this paper we focus on one of these methods, which is based on *empowerment* (Klyubin et al., 2008). Empowerment provides a "universal utility", i.e. a utility landscape over the state space of an agent which is defined purely by the agent-world dynamics. In contrast to other methods it does not focus on learning or exploration, but identifies preferable states in a known local environment. Empowerment considers the probabilistic map from a sequence of the agent's actions to a world state resulting from these actions as a channel; empowerment is then formally defined as the Shannon (1948) channel capacity of this channel. Essentially, empowerment is an information-theoretic generalization of the control-theoretic concept of controllability (Touchette and Lloyd, 2000).

The basic motivation behind the empowerment concept is that it is preferable to be in a state where the agent's actions have the largest influence on the perceivable world, or *Umwelt* (von Uexküll, 1909), of the agent. From an empowerment perspective, the ideal state to be in is one that offers a high number of choices that all lead to different outcomes that can be causally (and predictably) distinguished (i.e. controlled) by the agent. States to avoid are those where noise interferes with the influence of agent actions on its resulting state (lack of controllability), and those where the agent can only reach a low number of possible resulting states through its actions (lack of reachability). If we are dealing with a deterministic system, where each action leads to one specific outcome, then the criterion reduces to pure reachability. An example for the latter special case is given by Klyubin et al. (2005a) where he demonstrates the relationship between average distance and empowerment in a grid-world maze.

In this paper we continue prior work (Salge et al., 2012) which provides a fast approximation of empowerment using a Gaussian linear channel. Here, we expand this method to

allow empowerment computation based on the covariance matrix between actuators and sensors, which, importantly, allows for the incorporating of state-dependent noise. This provides us with an appropriate and fast empowerment algorithm for the study of continuous systems with several agents, which was not possible before. We will outline the modification for the approximation method, and then use it to examine the empowerment in a simple, continuous multi-agent system.

## Related Work

While many forms of adaptation and learning require some external goal-orientated supervision, critique, or perspective, it is now well understood, that a focus on embodiment (Pfeifer et al., 2007) provides a vehicle for self-determination which does not necessitate such external goals. Based on this, recent efforts have been made to understand agent control and agent motivation in the framework of the perception-action loop (Lungarella et al., 2005; Bertschinger et al., 2008), see also Fig. 1.

For example, Homeokinesis (Der et al., 1999) is a predictive methodology which adapts its perception-action loop on the fly, and drives an embodied agent to exploit its own embodiment to generate movement. It is related to other intrinsic motivation methods, such as “artificial curiosity” (Schmidhuber, 1991), or the “autotelic principle” (Steels, 2004), where the agent becomes self motivated when the challenges it faces are adequate for its skill level, inspired by the concept of “flow” (Csikszentmihalyi, 2000) for humans.

More recent developments use the framework of predictive information to produce intrinsically motivated robot control, generating behaviour only by looking at how specific actuator inputs change the agents sensor state (Prokopenko et al., 2006; Bialek et al., 2001; Ay et al., 2008). This is similar to the idea of empowerment, which is also fully defined by the channel between an agent’s actuators and sensors. One key difference though, is that empowerment provides a utility landscape by assigning a value to each state of the environment, where previous approaches are focussed on producing specific actions. Of special interest to the topic of this paper is also the work by Capdepuy et al. (2012), where he studies how empowerment is limited when several agents are using a joint channel, and what restriction this applies to agent coordination.

## Formalism

Given a perception-action-loop, as seen in Fig. 1, Klyubin et al. (2005a) defined empowerment as the channel capacity (Shannon, 1948) between an agent’s actuators  $A$  and sensors  $S$ , with the world being in state  $r \in R$ . Each state  $r \in R$  has its own empowerment value, which only depends on the

Figure 1: The perception-action-loop, unrolled in time  $t$ , visualised as a Bayesian network. The random variable  $S$  is the sensor of an agent;  $A$  is the actuator of an agent, and  $R$  represents the rest of the system.

channel between  $A$  and  $S$  in that state.

$$\mathfrak{E}(r_t) := C(p(s_{t+1}|a_t, r_t)) = \max_{p(a_t)} I(S_{t+1}; A_t | r_t). \quad (1)$$

Similarly, a sequence of  $n$  actions can be considered (called  $n$ -step empowerment), where the action-sequences are treated as a vector of random variables. The sensor state  $s \in S$  is then usually further in the future, and can also be a vector of random variables.

## Continuous Empowerment

Empowerment is defined for both discrete and continuous variables, but while it is possible to determine the channel capacity for the discrete case (for example by using the Blahut-Arimoto Algorithm (Blahut, 1972)), this is not generally possible for the continuous case. Jung et al. (2011) introduces a technique called Monte-Carlo Integration to approximate empowerment, but this method is very computationally expensive.

A faster method (described in detail by Salge et al. (2012)) to approximate the empowerment of a continuous channel is to treat it as a linear channel with added independent and identically distributed (i.i.d.) Gaussian noise.

$$S = TA + Z, \quad (2)$$

where  $S$  is an  $m$ -dimensional, continuous random variable,  $A$  is an  $n$ -dimensional, continuous random variable,  $T$  is a linear mapping, represented by a  $m \times n$  matrix, and  $Z_i \sim \mathcal{N}(0, N_i)$ , with  $i = 1, \dots, m$ , is another multi-dimensional, continuous, i.i.d. random variable, modelling isotropic noise in the sensor dimensions.

Assuming that there is a power constraint  $E(A^2) \leq P$  (without it the channel capacity would be arbitrarily large), this can be solved (Telatar, 1999) by applying a Singular Value Decomposition (SVD) to the transformation matrix  $T$ . The resulting singular values  $\sigma_i$  are then used to compute the channel capacity via the water-filling algorithm, as if this was a parallel Gaussian channel (Cover and Thomas, 1991). The channel capacity is then

$$C = \max_{P_i} \sum_i \frac{1}{2} \log(1 + \sigma_i^2 P_i), \quad (3)$$

where  $P_i$  is average power used in the  $i$ -th channel, following the constraint that  $\sum_i P_i \leq P$ . As the channel capacity achieving distribution is a Gaussian distribution, this means the optimal input distribution is a Gaussian with a variance of  $P_i$  for each channel.

### State-Dependent Noise

Salge et al. (2012) use simplifications that are only possible because the model's noise  $Z$  is assumed to be i.i.d distributed with a fixed variance. This forces the previous algorithm to assume the same level of noise for every state of the environment, and also makes it unable to model coloured, i.e. covariate, noise.

To address this problem we used the covariance matrix between actuators and sensors to capture the relationship between them, as well as the current noise level, and then reduced this problem to a parallel Gaussian Channel with i.i.d noise with the same capacity. First we chose  $n$  actuator variables  $A_1, \dots, A_n$ , and  $m$  sensor variables  $S_1, \dots, S_m$ . Now we determine the covariance matrix  $K$  between all these values. In our example, this is done by computing the pairwise covariance between sampled values for each of these variables. Alternatively, one could use the covariance function  $k(\cdot, \cdot)$  of a Gaussian Process that models the system to obtain the covariance matrix (not done in this experiment).

$$K = \begin{pmatrix} k(a_1, a_1) & \dots & k(a_1, a_n) & k(a_1, s_1) & \dots & k(a_1, s_m) \\ \vdots & \ddots & \vdots & \vdots & \ddots & \vdots \\ k(a_n, a_1) & \dots & k(a_n, a_n) & k(a_n, s_1) & \dots & k(a_n, s_m) \\ k(s_1, a_1) & \dots & k(s_1, a_n) & k(s_1, s_1) & \dots & k(s_1, s_m) \\ \vdots & \ddots & \vdots & \vdots & \ddots & \vdots \\ k(s_m, a_1) & \dots & k(s_m, a_n) & k(s_m, s_1) & \dots & k(s_m, s_m) \end{pmatrix} \quad (4)$$

$$= \begin{pmatrix} K_{a,a} & K_{a,s} \\ K_{s,a} & K_{s,s} \end{pmatrix}. \quad (5)$$

Now, if the variable  $A = A_1, \dots, A_n$  assumes a concrete value  $a = a_1, \dots, a_n$ , then this results in a specific, multi-variate Gaussian distribution for  $S = S_1, \dots, S_m$ , with

$$S = \mathcal{N}(\mu_s, K_s). \quad (6)$$

Note that  $K_s \neq K_{s,s}$ .  $K_s$  can be computed (Rasmussen and Williams, 2006) as:

$$K_s = K_{a,a} - (K_{s,a} K_{s,s}^{-1} K_{a,s}). \quad (7)$$

Assuming that the mean of actuator distributions of  $A$  is zero<sup>1</sup> we can also determine the mean for  $S$  given as a specific value of  $a$  as

$$\mu_s = K_{s,a} K_{s,s}^{-1} a. \quad (8)$$

We see from Equ. 7 that the covariance only depends on the original covariance matrix, and not on the actual value

<sup>1</sup> If the mean of a distribution is not zero it can be shifted without affecting the mutual information

of  $a$ . Also, from Equ. 8 we see that the new mean of the distributions is a linear transformation of  $a$ , with the matrix  $K_{s,a} K_{s,s}^{-1} = T'$ . So, a variation of  $a$  affects the mean of the resulting distribution of  $S$ , but not its covariance.

As a result, the relationship between  $S$  and  $A$ , as modelled by the covariance matrix, can be expressed as a linear, multiple input, multiple output channel with added coloured noise as

$$S = T' A + Z', \quad (9)$$

with  $Z' \sim \mathcal{N}(0, K_s)$ . Note, that there is no approximation in this step, the linear channel fully captures the dynamics of the system that are still present in the covariance matrix.

This can be further reduced to a channel with i.i.d. noise. For this, note that rotation, translation and scaling operators do not affect the mutual information  $I(S; A)$ . We start by expressing  $Z'$  as

$$Z' = U \sqrt{\Sigma} Z V^T, \quad (10)$$

where  $Z \sim \mathcal{N}(0, I)$  is isotropic noise with a variance of 1, and  $U \sqrt{\Sigma} V^T = K_s$  is the SVD of  $K_s$ .  $U$  and  $V^T$  are orthogonal matrices, and  $\Sigma$  contains the singular values. The square roots of the singular values scale the isotropic noise to the right variance; the noise is then rotated to resemble the original coloured noise. Note, that all singular values have to be strictly larger than zero, otherwise there would be a channel in the system without noise, which would lead to infinite channel capacity. Thus, we can consider  $\sqrt{\Sigma}^{-1}$ , a diagonal matrix with entries which are the inverse of the singular values in  $\sqrt{\Sigma}$ . This allows us to reformulate:

$$S = T' A + U \sqrt{\Sigma} Z V^T \quad (11)$$

$$U^T S V = U^T T' A V + \sqrt{\Sigma} Z \quad (12)$$

$$\sqrt{\Sigma}^{-1} U^T S V = \sqrt{\Sigma}^{-1} U^T T' A V + Z \quad (13)$$

$$\sqrt{\Sigma}^{-1} U^T S = \sqrt{\Sigma}^{-1} U^T T' A + Z V^T \quad (14)$$

$$\sqrt{\Sigma}^{-1} U^T S = \sqrt{\Sigma}^{-1} U^T T' A + Z \quad (15)$$

The last step follows from the fact that the rotation of isotropic Gaussian noise is isotropic Gaussian noise. This reduces the whole problem to a MIMO channel with isotropic noise with the same channel capacity. We simply define the transformation matrix  $T$  used in  $S = T A + Z$  as

$$T = \sqrt{\Sigma}^{-1} U^T T', \quad (16)$$

and apply the solution outlined for the simpler channel. This reduction allows the fast approximation of empowerment based on the covariance matrix between actuators and sensors, which can be either obtained via sampling of the environment, or by relying on a Gaussian Process Learner. This allows us to model the actual noise present in different states of the environment, which is then represented in the modified  $T$ .

## Model

We now apply this new method to a simple, continuous multi-agent system. The other agents are introduced to provide a changing level of noise in the environment. The covariance based empowerment approximation allows us to study how an agent would deal with different levels of noise.

### World Model

The model is a continuous, flat, two-dimensional world, populated by circular agents. Each agent has a radius  $l = 0.15$  meters<sup>2</sup>. Each agent is defined by:

- a position, stored in a vector  $q$ , which contains a real-valued  $x$  and  $y$  coordinate,
- a speed  $\dot{q}$ , expressing the change in  $x$  and  $y$  per second,
- a direction  $d$  the agent is currently facing, measured in radians, where 0 means the agent is heading north.

### Actuation

At the beginning of each time step, the agent has the choice to turn within its turning radius, which is 45 degrees, or one-eighth of a circle. The agent chooses a real value between -1.0 (turning 45 degrees counter-clockwise) and 1.0 (turning 45 degrees clockwise); 0.0 means the agent maintains its current heading. The agent turns instantaneously and then, for the duration of the time step, the agent continuously accelerates at  $0.03 \text{ m/s}^2$ . In our model the agent will accelerate at full power, the only choice is the direction of acceleration.

### Simulation

The only other acceleration force that applies to agents arises from collisions with other agents. Whenever the distance between two agents becomes less than the sum of their radii, a collision occurs. This is modelled as an elastic collision, so the agents can come closer than this distance, but will be subject to linearly increasing acceleration away from the center of mass of the other agent. The acceleration from the collision for the first agent can be computed as

$$\ddot{q}_c = \max(0, |l_i + l_j| - |q_1 - q_2|) \cdot (q_1 - q_2) \cdot c, \quad (17)$$

where  $c$  is a constant that determines how hard the elastic collision is. For lower  $c$ , colliding agents move further into each other before they bounce apart. Furthermore, to keep the velocity of the agents limited, there is a constant amount of friction applied to the agents. At each time step agents lose 5% of their velocity.

The progress of the model through time is simulated by breaking each time step into 20 pieces of equal length, and for each of those an appropriate fraction of the acceleration

<sup>2</sup>For ease of notation the unit length will be called meter, and the length of a time step will be one second

of the agent is added to its speed, and then the speed is added to the agent's current position. This is equivalent to explicit Euler integration.

Note that this model allows slip, i.e. an agent can head in one direction (where it is also accelerating to), while moving in a different direction. Turning does not change the current inertial movement.

## Experiments

### Hypothesis

Preliminary observations of the agent's behaviour indicated that an increase in the chance of a future collision with other agents is accompanied by a reduction in the current empowerment value. Therefore, our hypothesis for this simulation is that since the behaviour of other agents cannot be predicted, they will act as a source of noise in the environment, and colliding with them would be detrimental for an agent's empowerment.

### Different Scenarios

To test this hypothesis, and evaluate it systematically, we set up three different scenarios. In each scenario there are two agents. For the first agent we measure the empowerment and collision chance at different starting coordinates, located between -1 and 1, both for the  $x$  and  $y$  coordinate. The first agent is always heading north-east, and starts with a speed of  $0.03 \text{ m/s}$  in that direction. The second agent is always located in position (0.5,0.5) and is heading south-west with a speed of  $0.03 \text{ m/s}$ . The three scenarios differ in the behaviour of the second agent:

**Unpredictable Agent:** The second agent chooses actions uniformly random at the beginning of each time step, turning within its possible turn radius. The choice of the second agent cannot be predicted by the first.

**Predictable Agent:** The second agent always chooses to maintain its current direction, i.e. it moves in a straight line. This is known to the first agent, and incorporated into its model.

**Immovable Agent:** The second agent is anchored to its position, essentially constituting a fixed obstacle. It still reflects other agents colliding with it.

Note that the term agent here is used loosely as a "catch-all" term for other objects in the environment, which could be agents, movable objects or just fixed obstacles.

### Measurements

We computed the 4-step empowerment for Agent 1 for the three scenarios, for different starting positions. So, the actuation variables  $a_1, \dots, a_4$  denote what action Agent 1 chooses at the beginning of the first, second, third and fourth

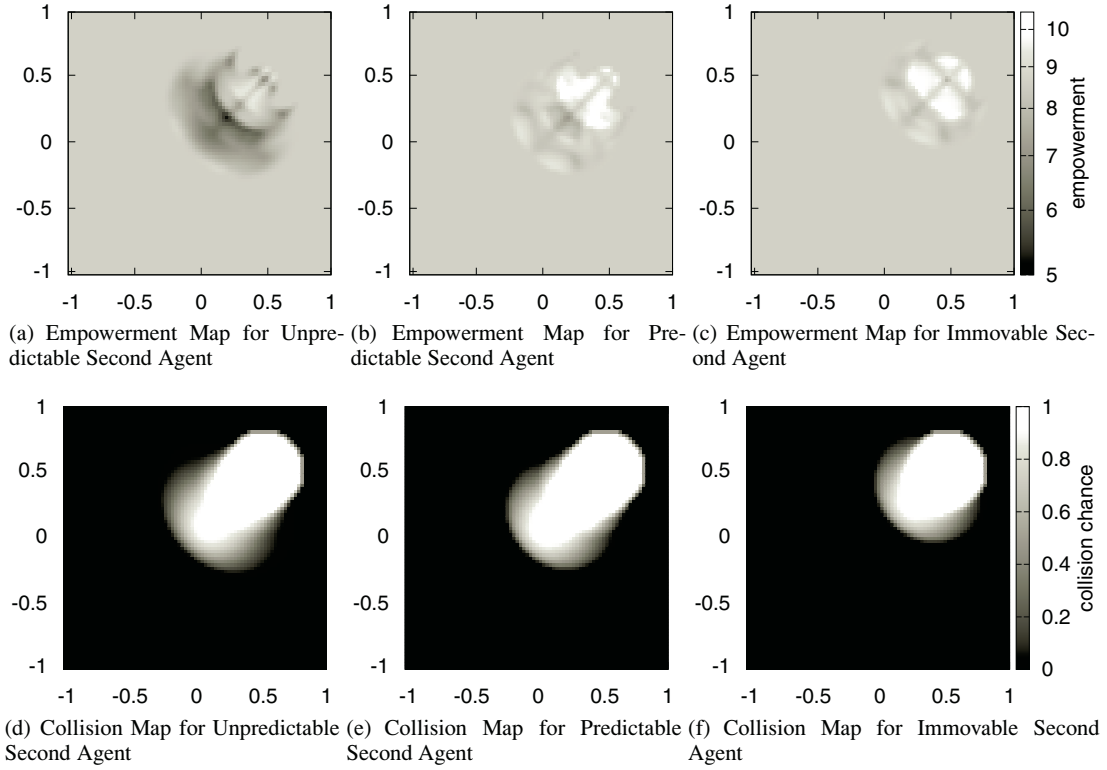

Figure 2: Plots of the empowerment and collision probability for different starting positions of the first agent. The Figs. 2(d)-2(f) show the fraction of action sequences that lead to a collision between the agents. Figs. 2(a)-2(c) show the empowerment of the first agent. The second agent is always located at position (0.5,0.5). Initial heading for the first agent is north-east, for the second agent it is south-west.

time step, respectively. The sensor input considered for empowerment were the values of  $x, y, \dot{x}, \dot{y}$  after the fourth time step, so the speed and position of the agent after the actuation sequence has been executed.

For each starting position for Agent 1, we used the actual simulation model to create an amount of samples, consisting of actuator variables and resulting sensor values. We used regular sampling, so that each time step the agent could only choose the 5 values of  $\{-1.0, -0.5, 0.0, 0.5, 1.0\}$ , leading to  $5^4 = 625$  possible action sequences in four steps. Each of these sequences was then simulated 10 times, leading to 6250 samples overall.

In the “unpredictable agent” scenario the action of the other agent was chosen uniformly random for those simulations, whereas in the predictable and unmovable agent scenario the simulation “knew” what the other agent would do, leading to a predictable outcome for each action sequence. So the 10 repeated samplings of the same action sequence only led to different results in the unpredictable agent scenario, since the pseudo-random generator would potentially chose different actions for the second agent. The resulting 8 times 6250 values were then used to pairwise compute a

covariance matrix between all 8 values (4 actuation values, 4 resulting sensor values), which was in turn used to compute the channel capacity from the actuation variables to the sensor values. This allowed us to compute empowerment of Agent 1 for different starting positions. We also recorded, for each starting position, what percentage of the sampled action sequences would lead to a collision with the second agent within the first four time steps.

## Results

The results demonstrate that colliding with the unpredictable agent leads to a substantial loss in empowerment, compared with the other scenarios. Consider first the collision maps depicted in Figs. 2(d)-2(f), which show what fraction of the action sequences in a given starting position leads to a collision between the agents. This segments the space of starting positions for agent one into three areas.

The area with zero collision probability are all locations where there is no chance for the agents to interact. These areas are thus of little interest for our central hypothesis. The empowerment landscape in these areas is constant, as expected for an unstructured environment. We will consider

this constant value to be the baseline value of empowerment for comparison.

The second area are those starting locations where the agents always collide. This is mainly a circle of diameter 0.3 *m* around (0.5,0.5), where the agents already start in collision, and a connected area where the agents start separated but are moving towards each other. Towards the center of the circle the agents overlap the most, and there are several areas of higher empowerment. This results from the specific collision mechanics in our simulation. As we model near-physical elastic collision, agents who overlap can be considered as “storing potential energy”, to apply a physical analogy. This high potential energy allows faster acceleration, which allows the agent to reach a greater variety of locations. The analogy here would be riding a bike, both on a flat surface, and starting on top of a hill. The extra speed gained riding downhill allows the rider to reach a greater variety of locations. Similarly, Agent 1 can control, in part, where this extra acceleration moves it, resulting in greater empowerment for Agent 1. We can also see that this effect is greater in Fig. 2(b) and Fig. 2(c), since the agent here can fully predict where this extra acceleration will lead it. In Fig. 2(a) this effect is less powerful, as the unpredictable movement of the second agent makes it harder to predict where the first agent will end up, thereby lowering the empowerment of Agent 1.

The most interesting area for our hypothesis are those locations where it is uncertain whether the agents collide or not. These areas are located further to the south-west of the second agent. So a first agent starting here is moving towards the second agent, but is far enough away that some actions might lead to an avoidance of collision. Now, the outcome of different action sequences not only depends on the first agent’s actions, but also on what the second agent does. If the second agent is unpredictable, i.e. moves at random, then the simulation done by the first agent will result in different outcomes for the same actions, introducing noise to the channel between actuators and sensors. This causes a measurable increase in uncertainty. The effect of this can be seen in Fig. 2(d). If we now compare this with the predictable second agent scenario, we see much less empowerment reduction with a predictable agent. While the second agent might still block access to some locations, it does not introduce noise into the outcome. Thereby, a collision with the second agent does not reduce the empowerment as much, as seen in Fig. 2(b). Similarly for the immovable agent, the empowerment here is only slightly reduced when an agent is on a collision course. So, the main cause for the drop of empowerment in our model is not the *collision* with a second agent, but the collision with an *unpredictable* agent.

### Empowerment Control

The difference between a predictable and unpredictable agent becomes even clearer if we look at the resulting agent

control. We implemented a greedy empowerment maximisation control. From five candidate actions (-1,-0.5,0,0.5,1) it picks the action that *leads to* the state with the largest empowerment value. For this, 4-step empowerment is calculated for all five states resulting from the candidate actions.

Fig. 3 shows the resulting trajectories of the first agent for different starting positions. Once a collision with the second agent occurs, the line becomes dashed. In both figures the first agent selects actions that maximise its empowerment for the next step; the only difference is the behaviour of the second agent. Both second agents start heading towards the first agent, but the second agent in Fig. 3(a) just moves straight, while the second agent in Fig. 3(b) moves at random. So in Fig. 3(b) the simulations of the first agent to determine the empowerment of possible future states cannot accurately predict the second agent. This means that the possibility to interact with the second agent becomes a source of noise, and empowerment maximisation avoids actions that lead to trajectories where the possibility of interaction with the second agent might arise. As a result, only three of the resulting trajectories collide with the second unpredictable agent. In the other case, shown in Fig. 3(a), empowerment sees no problem with colliding with the second agent, as it does not introduce noise into its action-perception channel and therefore it permits a lot of trajectories to end up in collisions.

### Discussion

The specific model we are considering here results in a collision avoidance behaviour regarding the second agent, if that agent is unpredictable. While it could be argued that other agents tend to be hard to predict, and therefore the assumption that other agents introduce noise is reasonable, we emphasize that the aim here was *not* to specifically produce obstacle avoidance. Also, the specific behaviour of empowerment depends on how the environment is modelled. If collisions result in loss of velocity, or even loss of actuation possibilities (like broken motors), then empowerment would avoid any collision. Even if this was not the case, if obstacle avoidance was desired, one could ‘spike’ the system dynamics as to make the agent believe that it would break down when it collides, which would induce strict obstacle avoidance. This would correspond to ‘programming’ or, rather, ‘nudging’ the empowerment-based behaviour engine towards desirable behaviours. Importantly, if there were an explicit goal of obstacle avoidance we would not contest that explicit obstacle avoidance algorithms would be superior. The advantage of an empowerment controlled agent lies in its universality. The same algorithm that avoids collision also balances an inverted pendulum (Jung et al., 2011), finds central positions in a maze (Klyubin et al., 2005b), can be used to adapt sensors (Klyubin et al., 2005a), and leads to the formation of patterns in multi-agent simulations (Capdepuuy et al., 2007).

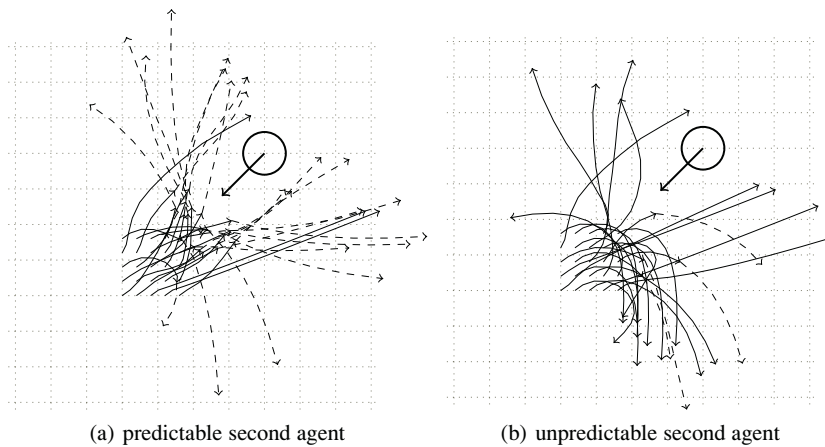

Figure 3: A comparison plot for the behaviour of an empowerment maximising agent. The arrows trace the trajectories of the empowerment controlled agent; each arrow is a different simulation, starting from a slightly different point. The initial heading of the empowerment agent is north-east. The circle indicates the starting position of the other agent, its initial heading is south-west. The lines become dashed if a collision between the agents occurs. Fig. 3(a) has a predictable second agent, which just moves straight ahead. Therefore, empowerment sees no need to avoid, and most trajectories lead to collisions. Fig. 3(b) has a second agent that chooses random actions. It is therefore a source of noise and the empowerment driven agent avoids colliding with it in most cases.

The point of using the intrinsic, empowerment-based behaviour is that it is more generic and grounded in the agent-system dynamics, and incorporates implicit difficulties that the agent may encounter. Thus, instead of imposing explicit conditions on when to activate a sub-behaviour, such as obstacle avoidance, one could incorporate desired hard behaviours, where required, into “surrogate” modifications of the physics of the system and let the empowerment-based behaviour engine generate the behaviours based on these modifications, whilst leaving the natural dynamics of the system unchanged for all other situations. Such an approach may be able to provide the agent with a more flexible repertoire of options, whilst respecting required hard constraints. It would also take a step towards “implicit programming”.

In terms of applications, it would also be interesting to see how an empowerment-based system would deal with a navigation task in a crowded environment, such as walking down Oxford Street at prime shopping time. In general, one should avoid colliding with people, but one could speculate that understanding how another person is going to move would allow an agent to operate closer to that person, with less chance of collision, and therefore less loss of empowerment. This would require the introduction of separate models for different agents, which would then allow an agent to model how predictable another agent is, and consequently adjust its behaviour towards different agents. Note that in this hypothetical example empowerment is clearly computed based on the agent model of the world. It does not matter how predetermined another agent’s behaviours are, but how well this can be predicted by the internal model.

More generally, we see that empowerment depends on the agent’s internal model of the world. Reducing the uncertainty in one’s internal model increases empowerment, which then raises the question, how suited is empowerment for exploration? We speculate that this depends on the horizon of the empowerment optimization. In the short term, interacting with another unpredictable agent will be detrimental, and avoiding it will preserve an agent’s empowerment. However, in the long term interacting with another agent might increase the predictability of said agent (by virtue of learning a better model of the agent), and this will improve the empowerment of the first agent on subsequent later interaction. This also indicates a more general distinction between different sources of noise in the environment; those that are unpredictable at first, but can be learnt, and those that are actually random.

## Future Work

In terms of robot control the development of both continuous empowerment (Jung et al., 2011) and fast continuous empowerment (Salge et al., 2012) was crucial to applying empowerment to real life systems in real time. The addition of state dependent noise now brings back the aspect of controllability to empowerment, and opens the possibilities for robotic control applications.

Imagine a robot that follows a human around in order to assist it. An empowerment map of the environment could provide the robot with an additional, supporting fitness function. Primarily, the robot would be interested in keeping its distance from the human. The reachability aspect of empow-

erment would keep it from getting stuck (actions would all lead to the same outcome), or ending up in a dead end. Controllability would keep the robot from getting too close to any human agent, considering they would be hard to predict. This could offer some additional incentives to the robot, once the primary objective is reached. So, instead of waiting, the robot could manoeuvre into a better position, where it could quickly get to a lot of other places, or where it would be less in danger of crossing paths with an unpredictable human agent.

## Conclusion

We demonstrated how state dependent, coloured noise can be integrated into the fast quasi-linear Gaussian approximation of empowerment. This allows this faster empowerment approximation to regain the state-dependent noise-sensitivity of the original formalism. The extension allows us to demonstrate with our examples how empowerment is negatively influenced by interacting with a local source of noise. We see that a greedy empowerment-maximising agent tries to avoid such interaction; in our specific case the collision with another agent. The same principle would apply to other forms of noise, i.e. other aspects of the environment that either cannot be, or have not been properly modelled by the agent.

### Abstract

Traditional models of ecosystems often assume that the species composing an unperturbed ecosystem become fixed so that only the relative abundances of the species change over time. Such ecosystems are said to have reached an optimal fixed point. However, recent work has suggested that neutral evolutionary processes can significantly alter the species composition of an ecosystem, allowing the ecosystem to exist in a dynamic steady state. Here, we investigate the stability of ecosystems and the nature of the equilibrium that forms using the digital evolution platform Avida, tracking evolving ecosystems over thousands of generations. We find that the communities that form are remarkably stable, and do not experience a significant loss of diversity in the long run even in experimental treatments where the communities suffer catastrophic population bottlenecks. When diversity rebounds, ecological communities are reconstituted in a different form than the one that was destroyed, but this difference is comparable to the difference the system would have accumulated if it had been left untouched. Thus, digital ecological communities exist in a dynamic steady state, which ultimately eliminates the effect of historical disturbances.

### Introduction

While the complexity of cellular and organismal biology is unquestionably stunning, it is often argued that the complexity of ecological communities is even more staggering, as they consist of co-adapted groups of organisms (Loehler, 2004). However, it is not immediately clear that ecological communities are necessarily any more complex. It is conceivable that general laws might guide the assembly, evolution, and even decay of ecosystems, simply because the interactions between species, as well as species with their environments, are simpler than the interactions between cellular components, or between cells within tissues that compose an organism. Indeed, simple ecosystems are usually modeled by systems of coupled differential equations that keep track of species and resource abundances (Tilman, 1982). In such models, ecosystems frequently exhibit an *ecological* steady state (Brock, 1967; Deakin, 1975; Aoki, 1988; Michaelian, 2005). In this state, resources flow through the system by being consumed and

replaced. Individuals come and go, but the species composition of the community is largely intact over large time scales. If this is so, then from the point of view of the species composition, the system has actually reached an *optimal fixed point*. In other words, the identity and frequency of a species is selected for, and does not change in the long run. Such ecological fixed points have been found experimentally in small systems (with a handful of species) (Rainey and Travisano, 1998) with evolution limited to only several weeks. Other experiments have found that communities will display different patterns of succession upon disruption by bottlenecks (e.g., in gut microbiota after administration of antibiotics), but the community ultimately arrives at a new stable state (Peterfreund et al., 2012).

It is difficult to ascertain whether any of these observations carry over to real ecological assemblies because tracking ecosystems over geological times is not possible, and modeling of such communities with standard methods such as systems of differential equations cannot shed light on this issue. While the stability of ecological communities can be studied (May, 1972, 1974; Montoya et al., 2006; Mougi and Kondoh, 2012), the existence of a dynamic steady state—where the community is constantly changing over evolutionary time scales and the only (approximate) constant is the number of species—cannot be studied because in the standard mathematical descriptions the number of possible participants is necessarily fixed from the outset. In contrast, in a dynamic steady-state, new species constantly emerge and established ones go extinct, while the ecological cohesion of the community remains intact.

If ecological assemblies are governed predominantly by neutral evolutionary processes (see, e.g., Chu and Adami 1999; Hubbell 2001; Volkov et al. 2003) rather than niche-specific adaptation, then dynamically changing fixed points should be expected. Here, we use digital evolution (Adami, 1998; Ofria and Wilke, 2004; Adami, 2006) as a tool to study the question of ecosystem evolution and stability from an “experimental” rather than mathematical point of view (see also Fortuna et al. 2013). We put the word experimental in quotes because not everyone is satisfied that what we learn

from digital experiments can carry over to biological assemblies of species. However, a significant amount of work with digital models has shown that they reproduce the basic phenomena associated with long-term evolution (Lenski et al., 2003; Wagenaar and Adami, 2004; Adami, 2006). Digital evolution experiments have even pointed to undiscovered effects in evolutionary theory (Wilke et al., 2001), which have subsequently been verified in “biochemicals.” The adaptive radiation of species in Avida has been studied previously (Cooper and Ofria, 2002; Chow et al., 2004; Walker and Ofria, 2013), but only a handful of studies have investigated the role of chance events on the outcome of evolution in digital systems. Previous studies on fluctuating environments, such as periods of resource scarcity (Yedid et al., 2008) and sudden changes in environment resource compositions (Wagenaar and Adami, 2004), and their effects on the evolution of specific tasks (i.e., specializing on a specific resource) have hinted that chance events do indeed affect the final outcome of evolution. Additionally, press (gradual) and pulse (instant) extinctions have been shown to alter the evolutionary path of a population enough to result in an entirely dissimilar final population (Yedid et al., 2009). Finally, an analysis of different forms of perturbations on digital ecosystems (such as mass extinctions) has shown that they affect the phylogenetic structure of the population, but leave little trace elsewhere (Yedid et al., 2012). These promising results highlight the need for more experiments studying the impact of historical contingency in the realm of digital evolution.

Here, we investigate the impact of population bottlenecks on the species composition of populations observed over the course of digital evolution. First, we show that population bottlenecks—even bottlenecks as small as a single organism—do not change the mean number of species in an ecosystem in the long run. Next, we provide evidence that populations evolve to use the same resources regardless of whether they experience a bottleneck. Finally, we demonstrate that while these populations use the same resources, the species that compose these populations do not remain at a single optimal fixed point. Rather, we suggest that evolving digital populations are in a dynamic steady state.

## Methods

We use the digital evolution platform Avida (Adami, 1998; Ofria and Wilke, 2004; Adami, 2006) to investigate the impact of population bottlenecks on populations of evolving digital organisms over long periods of evolutionary time. Avida has previously been used to investigate many fundamental aspects of evolution, including the evolutionary origins of complexity (Lenski et al., 2003), genetic organization (Misevic et al., 2006), adaptive radiation (Chow et al., 2004), and the division of labor (Goldsby et al., 2012). In this study, we subject the evolving populations to bottlenecks of varying size, then compare (1) the num-

Figure 1: An Avida population containing multiple genomes (left) and the internal structure of an individual organism, called an Avidian (right).

ber of species, (2) the resource usage of the entire population, and (3) the resource usage of individual species between each experimental treatment. With these three measurements, we experimentally determine whether chance events such as population bottlenecks can significantly alter the evolutionary result of an evolving population. In the remainder of this section, we describe the main features of Avida and the experimental design of the study presented in this paper. All experiments were conducted with Avida version 2.12.3, which can be freely downloaded from <http://avida.devosoft.org/>.

## Avida

Figure 1 shows a typical Avida population and the internal structure of a digital organism, called an Avidian. These Avidians metabolize resources and reproduce in a common environment that is split up into individual cells, where a single Avidian inhabits each cell. During their lifetime, the Avidians execute their genome—a circular list of assembly-like instructions—using their virtual CPU. Executing these instructions allows the Avidians to perform various tasks in the environment (e.g., metabolize resources, described in more detail below), which can be thought of as the Avidian’s phenotype. In this study, each Avidian’s virtual CPU contains a circular list of three general-purpose registers, two general-purpose stacks, and four special-purpose heads, which are pointers into the Avidian’s genome, similar to a traditional program counter and stack pointer.

Further, each Avidian in this study is self-replicating, which means that it must contain instructions in its genome to copy itself and produce an offspring. During the self-replication process, the genome copy experiences mutations that change a single instruction to a different random instruction. Once the Avidian finishes copying itself, the copy is placed into a random cell elsewhere in the environment, i.e., the population is well-mixed. If the chosen cell is already inhabited by another Avidian, the existing Avidian is replaced by the new Avidian. By repeatedly following this metabolism-replication-mutation process, the Avid-

ian population is able to evolve and adapt to the environment over long time periods.

The Avida environment can be thought of as a “digital chemostat,” where simulated resources are constantly flowing in and out of the environment at predefined rates. Avidian genomes change over evolutionary time, and adapt to perform various logic tasks (e.g., AND, OR, and XOR), because the performance of such tasks is rewarded by “SIP” (single instruction processing) units. Each SIP unit gives an Avidian the ability to execute exactly one instruction, and can be thought of as the digital equivalent of ATPs, which power biochemical cells. Without SIPs, Avidian genomes cannot be executed. In order to perform a logic task, the Avidian program must have the correct sequence of instructions to input random binary numbers from the environment, perform a computation on them using a single logic instruction available to them (NAND), then write the resulting value back into the environment. At the same time, a resource associated with that logic task must be present in the environment. Because complex logic operations (such as EQU and XOR) can and must be built from simpler ones, Avidians must evolve the equivalent of metabolic pathways, only on a computational level. As an Avidian metabolizes more and more resources over its lifetime, it is able to execute more instructions faster than Avidians that have not metabolized any resources. Consequently, Avidians are indirectly selected to adapt to their environment and consume the available resources in the digital chemostat.

In this study, we use the “resource-9” environment, in which 9 logic tasks (NOT, NAND, AND, ORN, OR, ANDN, NOR, XOR, and EQU) are rewarded equally for completing them. The resource associated with each task flows into the digital chemostat at a fixed rate of 10 units/update. In general this rate can be varied, but we chose here the level at which the highest speciation rate was observed in Chow et al. (2004). Each Avidian can only consume each particular resource up to 5 times per update. Because resources are limited, the average amount of resource an Avidian consumes is proportional to the mean abundance of that resource across the population. In this limited resource environment, generalists that consume all 9 resources are selected against because they would consume each and every resource to the point that the net benefit of generalization is smaller than if each species specializes on one resource. As a consequence, mutants that evolve to tap into an unused resource have an advantage at first, and over time communities assemble that divide up the resource space roughly equally (as each resource is valued the same).

Any settings differing from the Avida defaults are described in Table 1. These settings are drawn from Chow et al. (2004) to replicate their Avida adaptive radiation experiments.

Setting	Value
Copy mutation rate	0.005
Insertion/deletion mutation rate	0.0
Min/max genome length	100
Max population	3000

Table 1: Custom Avida settings for this study.

## Control and bottleneck experiments

As a control, we first perform a set of Avida experiments for  $10^6$  updates with no population bottlenecks. These experiments provide a base expectation for what the evolved communities should look like if bottlenecks have no impact on the evolutionary outcome of a population. Next, we carry out another set of Avida experiments for  $10^6$  updates, but with the populations experiencing a single bottleneck of varying sizes (1, 5, 10, 20, 100, 200, 300, 400, and 500) at update  $5 \times 10^5$ . We execute the bottleneck procedure by removing random Avidians from the population until the population is reduced to the desired bottleneck size. After the bottleneck is applied, we allow the population to evolve without intervention for the remaining  $5 \times 10^5$  updates.

We initialize each Avida experiment with the same default ancestor, an Avidian with a genome length of 100 that is only capable of self-replicating. We repeat each experiment in replicate 100 times with random number seeds of 1-100. Before every bottleneck and at the end of every Avida run, we record the entire current population and the population history for use in a species clustering algorithm (in order to count species), described below. In addition, we collect the standard Avida statistics (averages, counts, resource, tasks, etc.) every 100 updates to perform population resource usage comparisons.

## Species clustering algorithm

To determine the species present in a population, we employ the species clustering algorithm from Chow et al. (2004), which clusters species based on phylogenetic distance. We calculated the phylogenetic distance between two Avidians by counting the number of ancestors between them along the lines of descent leading to their last most recent common ancestor. First, the algorithm requires the user to calibrate a threshold phylogeny depth value ( $T$ ) by calculating the  $T$  value necessary for the clustering algorithm to predict  $\leq 25\%$  of runs having 2 species,  $\leq 2.26\%$  of having 3 species, and  $\leq 0.1\%$  showing 4 species, when the algorithm is run on a set of 100 or more Avida runs with unlimited resources. It is known that when resources are unlimited, generalists will evolve, and the community will have exactly one species (Cooper and Ofria, 2002; Chow et al., 2004). With this calibrated  $T$  (here,  $T = 200,142$ ), the clustering algorithm then forms clusters of species in the reconstructed phylogeny by grouping genotypes less than  $T$  away from the

Figure 2: Average number of species for differing experiments based on the phylogenetic depth clustering algorithm. Each experimental treatment is listed along the bottom. The control experiment is labeled “C” and the bottleneck experiments are labeled with the size of the bottleneck. Error bars are two standard errors over 100 replicates.

computed genotype “species basins.” After the clustering algorithm identifies all of the species clusters, it outputs (1) the number of species and (2) the representative genotype of each species basin. This output allows us to compare species counts and species resource utilization between experimental treatments with and without population bottlenecks to determine whether the bottleneck had a significant effect on the evolutionary outcome of the population. The number of species predicted by this algorithm compares well with the “ecological” number of species, which is obtained by turning off mutation rate and counting the number of genotypes that remain in equilibrium after a long time (Cooper and Ofria, 2002; Chow et al., 2004).

### Difference in resource usage

After identifying the species for a given time point, we use Avida’s Analyze mode to determine each of the species’ resource utilization vector  $\vec{\phi} = (\phi_1, \phi_2, \dots, \phi_9)$ , where  $\phi_r$  is the average number of times the species has obtained resource  $r$  (associated with task  $r$ ) during its lifetime. We then normalize this vector so that the  $\phi_r$  of the resource that is used most by that species is set to 1.0.

In order to calculate the difference in resource usage between two species  $i$  and  $j$ , consider two resource utilization vectors  $\vec{\phi}_i$  and  $\vec{\phi}_j$ . We define the difference in utilization between those species as the Euclidean distance  $d_{ij} = |\vec{\phi}_i - \vec{\phi}_j|$ . What is the difference between two communities? If community  $C_a$  is defined by the assembly  $C_a = (\vec{\phi}_1, \dots, \vec{\phi}_n)$  and community  $b$  by  $C_b = (\vec{\phi}_1, \dots, \vec{\phi}_m)$ , we first pad the assembly vector  $C$  of the community with the smaller number of species with null vectors, and define

the assembly difference matrix as

$$D_{ij}^{(ab)} = |\vec{\phi}_i^{(a)} - \vec{\phi}_j^{(b)}|, \quad (i, j = 1, \dots, n). \quad (1)$$

Because this distance depends on the ordering of species in the community vector, we define the community distance  $D$  as the minimum of the trace of the distance matrix, minimized over all permutations of the species order. Thus, let  $P$  be a permutation matrix (of the set of  $n!$ ). Then

$$D = \min_P \text{Tr}(PD^{(ab)}). \quad (2)$$

In other words, to find the difference between two communities, we compute all pairwise distances between the species of both populations. If both communities are identical, the sum of the diagonal of this pairwise distance matrix must be 0.0, but only if we have correctly matched all species. If the populations have a different number of species, we supplement the population with fewer species with a species using no resources. To perform the match, we test all permutations of the distance matrix (i.e., with different species orders) to minimize the trace (the sum of the diagonal elements) of the matrix. This measure provides the minimum distance between two communities in species resource usage space.

## Results

### Species counts

Figure 2 shows the species counts based on phylogenetic depth for the control experiment in comparison to the varying bottleneck experiments. On average, the control resulted in  $3.55 \pm 0.22$  species (mean  $\pm$  two standard errors) and none of the experiments resulted in a significantly different species count. It is interesting to note that even experiments with a bottleneck size of only one organism did not have their ultimate species counts significantly impacted.

### Comparison of task distributions

Next, we compare the average population resource usage

$$\vec{R} = \frac{1}{N_{\text{tot}}} (N_1, \dots, N_9), \quad (3)$$

where  $N_r$  is the number of times resource  $r$  has been consumed by the population *per update*, and  $N_{\text{tot}} = \sum_{i=1}^9 N_i$ , for the final populations of each experiment. Differences in  $\vec{R}$  allow us to examine if there is a significant difference in overall resource usage before and after bottlenecks of different sizes.

Figure 3 shows the  $\vec{R}$  of the final control and bottleneck populations. Qualitatively, there appears to be little difference in the resource usage between the different experiments, indicating that the populations recovered from the bottleneck and eventually reconstituted an ecosystem that consumes resources at a rate comparable to an untouched

Figure 3: Average fraction of tasks performed per update  $R_r$  (defined in Equation 3) by the Avidians in the final population of different experiments over 100 replicates. The experiments are listed along the left side. The control population at update  $10^6$  is labeled “C” and the experimental populations are labeled with the size of the bottleneck. Each task along the bottom is a logical function in Avida which can be considered a resource that a digital organism can adapt to metabolize.

ecosystem. To confirm our qualitative analysis, we compute the Pearson correlation coefficient between the  $\vec{R}$  of the bottleneck populations and the control populations. The smallest correlation is between the control populations and the 5-organism bottleneck experimental populations ( $\rho = 0.98$ ), which still indicates a strong correlation in the resource usage vectors. Thus, even the most severely bottlenecked populations reconstituted the same resource usage after a long period of evolutionary time, even though the species composition could be very different. Similar overall resource usage by different communities could be an indication of *functional redundancy* (Tilman et al., 1997; Wohl et al., 2004).

### Comparison of individual species resource usage

The populations evolve to use the same resources over all experimental conditions, but the species within a population (the community assembly) may look very different from one experiment to another. To establish a baseline, we look at the differences in species resource usage among the experimental populations after  $5 \times 10^5$  updates. Shown in Figure 4, we compute the mean difference in species resource usage between communities evolved in 100 independent populations (excluding a direct comparison of a population with itself) and find  $D = 2.26 \pm 0.025$ . With this measure, we characterize the differences that arise in communities simply because each population takes its own historical path.

Next, we compare the communities between the reference populations at  $5 \times 10^5$  updates to two sets of populations at update  $10^6$ : One set of control populations that never experienced a population bottleneck, and another set of experimen-

Figure 4: Overview of the population's species resource usage differences. The values shown are the mean difference  $D$  ( $\pm$  two standard errors) between and within populations. All populations from update 0 (labeled “origin”) to update  $5 \times 10^5$  had the same evolutionary history. At update  $5 \times 10^5$ , the experimental populations (labeled “bottleneck”) experienced a single bottleneck reducing the population to one organism, whereas the control populations (labeled “control”) were untouched. After the treatment at update  $5 \times 10^5$ , the populations were then allowed to evolve for another  $5 \times 10^5$  updates. The resulting populations are labeled “update 1,000,000.”

tal populations that experienced a severe population bottleneck (a single organism) at update  $5 \times 10^5$ . We found that there was no significant difference in inter-population differences between the reference populations at update  $5 \times 10^5$  (mean  $\pm$  two standard errors,  $D = 2.66 \pm 0.025$ ) and the control population at update  $10^6$  ( $D = 2.61 \pm 0.025$ ). In contrast, the inter-population differences within the experimental populations were significantly reduced ( $D = 1.94 \pm 0.029$ ).

While populations evolve to use the same resources regardless of treatment (Figure 3), it is not clear whether or not the populations are at a dynamic steady state or an optimal fixed point. If the populations do not change over evolutionary time (i.e., the populations are at an optimal fixed point), we would expect the difference in species resource usage between the baseline populations at update  $5 \times 10^5$  and the control populations at update  $10^6$  to be minimal, if not 0.0. Instead, when comparing each control population at update  $10^6$  with its corresponding reference population at update  $5 \times 10^5$ , we observe that the populations are composed of significantly different species (Figure 4,  $D = 2.07 \pm 0.24$ ). Additionally, we find a significant difference when performing the same comparisons between the reference populations and experimental populations that experienced a population bottleneck ( $D = 1.93 \pm 0.27$ ). This is the same difference that we find when we again perform the same comparison between the control populations and experimental populations at update  $10^6$  ( $D = 2.14 \pm 0.27D$ ). Thus, although

Figure 5: Mean difference  $D$  in species resource usage between the populations at update  $5 \times 10^5$  and the populations at update  $10^6$ . Each experimental treatment is listed along the bottom. The control populations are labeled “C,” whereas the bottleneck populations are labeled with the size of the bottleneck. Error bars are two standard errors over 100 replicates.

the experimental populations are significantly different from the reference populations, they are just as different as they would have become if they never experienced a population bottleneck. Together, these data highlight our two major findings:

- (1) population bottlenecks do not have a significant effect on the species composition of a population over long evolutionary periods, and
- (2) over sufficiently long evolutionary periods, populations are in a dynamic steady state rather than at an optimal fixed point.

In a catastrophic population bottleneck, only one organism survives the bottleneck, which effectively destroys the ecosystem and reduces the number of species to 1. By subjecting the populations to such a severe population bottleneck, the population is forced to re-evolve every other species, which may explain the results above. What if the populations experience a less severe population bottleneck? A less severe population bottleneck would preserve most, if not all, of the ecosystem and its species. In Figure 5, we further demonstrate that regardless of the population bottleneck size, populations do not maintain an optimal fixed point. Additionally, we show in Figure 6 that regardless of the population bottleneck size, all experimental populations at update  $10^6$  have the same difference from the control population at update  $10^6$ . Thus population bottleneck size does not affect the species composition of populations over sufficiently long evolutionary periods.

Figure 6: Mean difference  $D$  in species resource usage between the control populations at update  $10^6$  and the bottleneck populations at update  $10^6$ . Each experimental treatment is listed along the bottom. The bottleneck populations are labeled with the size of the bottleneck. Error bars are two standard errors over 100 replicates.

## Discussion

Competition over resources shapes ecological communities, and creates assemblies that are highly adapted to their environment. Species (or ecotypes in microbial communities) can only be maintained if they are adapted to different niches, which means that they must each “make a living” differently. In our model system, this means that each species must specialize to predominantly use a different resource. Here we have asked: Once an ecosystem is established, will it maintain its species composition over long periods of time (i.e., an optimal fixed point), or do species continue to change over evolutionary time (i.e., a dynamic steady-state)?

We find that populations evolve the same number of species regardless of the bottleneck size, and that the number of species in a population is much smaller than the number of available resources (on average around 4, compared to the theoretical maximum of 9). Each population has approximately the same distribution of consumed resources, again regardless of experimental conditions. Analyzing populations in detail, we find that species partition the resources (i.e., niches) in many different ways, and continue to do so during evolution. While technically speaking, no new species form after the establishment of a community (as opposed to what is observed in perfectly neutral models of species diversity, e.g. de Aguiar et al. (2009), where the rate of speciation is constant over time), we notice that the species themselves continue to change, and the community with them. Applying bottlenecks of different sizes, including catastrophic events where only a single organism survives, has no effect on this phenomenon. Ecosystems re-

form after the catastrophic event (either in a form similar to the community before the event, or differently), but continue to change thereafter. Thus, evolving ecosystems resemble a dynamic steady-state rather than an optimal fixed point.

These results have significant implications for experimentalists who work with biological systems that require regular bottlenecks on the population to conduct the experiment, e.g., the *E. coli* long term evolution experiment (LTEE) (Lenski, 2011). This study demonstrates that these regular population bottlenecks do not affect the long-term evolution of populations, nor do they significantly affect the species composition of the population in the long-term. We note that at least one population of the LTEE seems to have developed a community of coexisting types (Blount et al., 2012).

Prior biological experiments suggested that population bottlenecks imposed on ecological communities leads to several waves of succession followed by the establishment of a new stable state with a similar degree of diversity compared to the initial stable state (Peterfreund et al., 2012). These experiments, however, were all conducted on a very short time scale. We evolved our populations for 25,000 generations between measurements (assessment of species composition), which allows for much more neutral evolution. We note that in these experiments, each of the 9 possible resources were worth the same to an Avidian, i.e., switching from one resource to another would not be beneficial (nor detrimental) as long as the concentration of that resource in the community is the same. It is possible that this setting creates more neutrality in the landscape compared to a setting where each resource has a distinct metabolic payoff, and it would be interesting to study a fitness landscape with different metabolic payoffs in detail in future work.

It might also seem surprising that we observe drift in the community even though the number of species in the community is quite low (between 2-6, on average). Most of the interesting biological communities consist of many more species: It has even been suggested that soil microbial communities could harbor up to  $10^6$  species (Gans et al., 2005). It would be interesting to test community drift and turnover when there are an order of magnitude more niches to be occupied, which can be done in Avida by placing digital organisms in the “logic-77” environment, giving 77 distinct niches. We have also not addressed the effect of trophic levels on ecosystem stability and turnover. Recent modeling efforts (Mougi and Kondoh, 2012) suggest that the variety of trophic interactions stabilize these communities, which could in principle lead to a reduction in community drift.

## Conclusions

We found that populations of digital organisms exposed to an environment with limited resources rapidly radiate to take advantage of the available niches, but that the rate of speciation stops long before all niches are occupied. Severe bottle-

necks can destroy these communities, but stable communities rapidly re-evolve, albeit with a different species composition. We have shown that the species composition of these communities is not affected by bottlenecks of any size in the long run, simply because these communities are in a state of constant flux anyway: The communities form dynamic steady-states, where the species are constantly changing the resources they specialize on. While the evolved communities are resistant to invasion (Chow et al., 2004), they are not resistant to change. Because the available niches can be occupied by a multitude of functionally similar or even identical species (and perhaps because each resource in the logic-9 environment is worth the same), the communities themselves are subject to a considerable amount of drift, even when the community as a whole remains cohesive. The communities are resistant to invasion due to the particular trade-offs each species has incurred in its adaptive specialization. In this respect, Avidian communities behave much as predicted by Tilman’s “stochastic niche theory” (Tilman, 2004): They are dominated by both adaptive forces (generating the trade-offs) as well as neutral forces (stochastic assembly and drift). Thus, we suggest that further experimentation with Avidian ecosystems can generate significant progress in our understanding of ecological theory and experiments.

# Prebiotic Evolution of Molecular Assemblies: From Molecules to Ecology

Markovitch Omer<sup>1</sup> and Lancet Doron<sup>1</sup>

omermar@gmail.com

## Abstract

Present life portrays a two-tier phenomenology: molecules compose supramolecular structures, such as cells or organisms, which in turn portray population behaviors, including selection, evolution and ecological dynamics. Prebiotic models have often focused on evolution in populations of self-replicating supramolecules, without explicitly invoking the intermediate molecular-to-supramolecular stage. We explore a prebiotic model that allows one to relate parameters of chemical interaction networks within molecular assemblies to emergent ecological and evolutionary properties in populations of such assemblies. We use the graded autocatalysis replication domain (GARD) model, which simulates the network dynamics of amphiphile-containing molecular assemblies, and exhibits quasi-stationary compositional states termed *compotypes*. These grow by catalyzed accretion, divide and propagate their compositional information to progeny in a replication-like manner. The model allows us to ask how molecular network parameters influence assembly evolution and population ecology, analyzable by a multi species logistic (r-K) model for population ecology (Lotka-Volterra competition model). We found that *compotypes* with a larger intrinsic molecular repertoire show a higher intrinsic growth (r) and lower carrying capacity (K), as well as lower replication fidelity. This supports a prebiotic scenario initiated by fast-replicating assemblies with a high molecular diversity, evolving into more faithful replicators with narrower molecular repertoires. A main difference from classical ecology is that in GARD species inter convert into each other rather than consume each other or compete on resources, thus representing ‘fast forward’ of speciation.

## Introduction

The path from organic mixtures (i.e., the primeval soup) to reproducing life-like protocells no doubt required the emergence of replicating systems capable of undergoing Darwinian evolution. Therefore, uncovering how such entities emerged in early niches will greatly contribute to our understanding of life’s origin and can potentially allow one to design novel experiments. The GARD model (Segre, Ben-Eli, Lancet 2000) in the realm of the lipid world scenario (Segre, Ben-Eli, Deamer et al. 2001) offers one possible route for such pursuit. In this framework, non-covalent assemblies of amphiphiles, such as lipid micelles or vesicles are studied. These store information in the form of nonrandom molecular compositions, which is passed to progeny via homeostatic growth accompanied by fission. The model quantitatively describes the details of such a process (Segre et al. 2000). It is based on a directed catalytic network (termed  $\beta$ ), whose nodes and edges respectively represent molecular types and catalytic

rate enhancements. Importantly, the system is kept away from thermodynamic equilibrium by assembly fission, which produces two progeny assemblies. Key in GARD dynamics are *composomes*, replication-prone quasi-stationary states. A group of *composomes*, gleaned by clustering, is termed *compotype*, and may be regarded as species in the framework of lipid world and GARD. Indeed, such GARD species were recently shown to display a significant measure of Darwinian evolution (Markovitch and Lancet 2012), in disagreement with a report (Vasas, Szathmáry, Santos 2010) criticizing this notion on the basis of testing random compositions and with no statistical rigor.

## Simulations

The GARD10 MATLAB code was employed for all simulations, using parameter values identical to those employed previously (Markovitch and Lancet 2012). The dynamics of compositional assemblies in a reactor under constant population conditions were examined. The reactor is seeded with 1,000 random compositions which are allowed to simultaneously grow based on their idiosyncratic kinetic parameters, and undergo fission when reaching a predefined maximal size. The pre-fission composition of each assembly is assessed as belonging to one of the *compotypes* characterizing the specific  $\beta$  or to “drift”.  $C_i$  marks the fractional number of assemblies belonging to *compotype*  $i$  (out of 1,000). Each simulation is performed for 50,000 split events in the reactor, typically sufficient to reach steady state in *compotype* frequencies. For statistical rigor, 1,000 such simulations were performed, each with a different  $\beta$  whose edges are randomly drawn from a lognormal distribution (Segre, Shenhav, Kafri et al. 2001).

## GARD Population Dynamics

Different simulations showed widely different dynamic behaviors, such as non-trivial “takeover” of a fast-rising *compotype* by a slower one (Fig. 1). Such dynamics is typical of natural ecosystems that harbor multiple species with competition or predator-prey relationships. The results were analyzed by a multi species logistic equation (May 1974; Gabriel, Saucy, Bersier 2005) (Fig. 1 legend). The GARD model thus affords a unique opportunity to directly relate molecular parameters to ecological behavior, bypassing the organismal complexity that usually bridges the two. As an example, the relationship between a *compotype*’s molecular

diversity and two central quantitative ecological parameters are portrayed here.

**Fig. 1:** An example of population dynamics. Broken lines represent the three compotype species found in this simulation and solid lines are a fit to the logistic growth:  $dC_i/dt = r_i C_i [K_i - C_i - \sum_j (\alpha_{ij} C_j)] / K_i$ , where  $C_i$  is the population-fraction of compotype  $i$  in the population at time  $t$ . Fitted parameter values are:  $r_{1,3} = 5e-3, 4e-3, 2e-3$ ;  $K_{1,3} = 0.56, 0.49, 0.72$ ;  $C(t=0)_{1,3} = 0.019, 0.003, 0.055$ ;  $\alpha_{12}=1.5, \alpha_{13}=0.05, \alpha_{21}=0.8, \alpha_{23}=0.56, \alpha_{31}=1.3, \alpha_{32}=0$ .

### Compotype Molecular Diversity

The chemistry to ecology transition was done by analyzing populations of GARD assemblies through the scope of multi species logistic growth. In this analysis, each compotype species  $i$  is characterized by two basic parameters: the intrinsic growth rate ( $r_i$ ) and the carrying capacity ( $K_i$ ).

The simulations result in the generation of about 1,500 compotypes in 1,000 chemical niches ( $\beta$  networks). Compotypes are defined at their molecular level by  $N_{mol}$ , the size of the intrinsic molecular repertoire of the compotype. In a simulation with  $N_G$  molecular types,  $N_{mol} < N_G$  represents the subset of molecule types present as a result of the intermolecular catalytic interactions in  $\beta$ . It is found that  $K$  values are inversely correlated with  $N_{mol}$ . In contrast,  $r$  values show a weak positive correlation (Fig. 2). Thus, in the absence of competition, the time-dependent prevalence of compotypes with large  $N_{mol}$  will show a steep ascent with a relatively low plateau, while those with low  $N_{mol}$  will show a slower ascent but can potentially reach a higher plateau.

Of note, an analog trend to the increase of the intrinsic growth rate with molecular diversity was observed in experimental data for 113 Bacteria (Freilich, Kreimer, Borenstein et al. 2009), whereby a negative correlation between measured doubling time and metabolic network size was found. The results might advocate for a prebiotic scenario initiated by fast-replicating assemblies with a high molecular diversity, evolving into more faithful replicators with narrower molecular repertoires. This is not unlike the transition from prebiotic “random chemistry” to the relatively restricted repertoire of small molecules (monomers) seen in present-day living cells (Segre et al. 2000).

### Compotype Replication Fidelity

In the absence of competition, i.e. when examining simulations exhibiting only one compotype species, a

**Fig. 2:** Compotypes dependence of carrying capacity ( $K$ ) and intrinsic growth rate ( $r$ ) on the size of the intrinsic molecular repertoire of compotypes ( $N_{mol}$ ). Data is binned.

compotypes'  $K$  values typically does not reach the upper limit of 1.0 (mean  $K=0.54 \pm 0.35$  for such simulations).  $K$  represents the maximal number of individuals that may be sustained in an environmental niche. In the original Verhulst formalism, death was introduced by as a potential solution to the Malthusian exponential growth, and later in the r-K formalism  $K$ =birth/death (Gabriel et al. 2005). In GARD, a similar interpretation of  $K$  pertains, whereby a positive correlation between  $K$  and replication fidelity ( $F_{rep}$ ) is observed:  $K=6.2 \cdot F_{rep}-5.35$  with  $R^2=0.63$ .  $F_{rep}$  measures the average degree of compositional similarity between a compotype assembly to its fully grown progeny. Thus, unfaithful replication means that the fully grown progeny has lost its compotype state and is considered drift, somewhat comparable to death.

## Abstract

The fast grow of expectations from robots and the technical obstacles the robot developers face when trying to meet the requests, force an orientation towards designing and controlling robots by following biological paragons. This tendency increases interest in human-robot analogy, and the present work is a part of this stream. The paper questions the voluntariness of human motion by relating it to physiological processes. We concentrate on the important question of redundancy. One notes that humans do not resolve the redundancy on the level of consciousness, except in some specific examples (like obstacle avoidance), but rather on a lower level of decision-making – the human reaction to the faced problem is somehow "automatic". We suggest that this automatism is closely related to physiological processes, particularly to the progress of fatigue. Then we try to mathematically model these processes and their influence to human motion. The mathematical model of fatigue progress is derived as well as an algorithm for human-like redundancy resolution. We finally consider the implications of the obtained results to anthropomimetic robotics. The concept is verified by simulating the system behavior and comparing it qualitatively with the behavior of a human control group.

## Introduction

In the last decade we witness the fast growing interest in technical systems, in particular robots, mimicking living beings. A new class of robots have appeared – anthropomimetic robots – imitating humans regarding their mechanical structure, actuation, and intelligence (Holland & Knight, 2006; Diamond, et al., 2012; Potkonjak, et al., 2011; Wittmeier, et al. 2013; Mizuuchi, et al., 2007; Sodeyama, et al., 2008). Mimicking humans is an ultimate response to the increasing expectations and complexity of tasks imposed to robots, on one hand, and the technical and technological obstacles robot developers face when trying to meet the requirements, on the other.

With such approach the deep relations between motion/actuation, intelligence, and physiological processes have to be explored. For instance, motion used to be considered as a purely voluntary action resulting from consciousness and intelligent process. This was specially the case with robots where the voluntariness of motion was almost an axiom. However, the new concepts question this viewpoint. Regarding consciousness, it has been found that with humans a motor activity starts even before we are aware of the intention (Haggard & Libet, 2001). Researchers have also recognized the significance of morphology and motor

activities in shaping human intelligence (Pfeifer & Bongard, 2007). The present work does not elaborate these interesting problems but questions the voluntariness of human motion from another standpoint being dependant on the physiological processes. We concentrate on the important question of redundancy. The kinematic redundancy is normally present in humans and accordingly in anthropomimetic robots as well, offering multiple choice when deciding about joint motions that will execute some given end-effector motion task (e.g., some manipulation in space). One notes that humans do not resolve the redundancy on the level of consciousness, except in some specific examples (like obstacle avoidance), but rather on a lower level of decision-making – the human reaction to the faced problem is somehow "automatic". We suggest that this automatism follows from physiological processes, particularly from the progress of fatigue. Then we try to mathematically model these processes and their influence to human motion, to finally see whether the obtained results have sense and implications in anthropomimetic robotics. Human-like reactions of robot to overloading and a kind of human-like communication have been achieved.

## Background Research and the New Concept

### Kinematic Redundancy

From a mechanical point of view, a human and a robot resembling a human are kinematically redundant, i.e., their mechanisms feature a higher degree of mobility than required for a given motion in operational space. Kinematic redundancy contributes to motion dexterity and facilitates coping with unpredictable changes within its environment. Some advantages resulting from redundancy are exploited on the level of consciousness and intelligence (e.g., avoiding obstacles in the workspace) while others are exploited automatically, on a lower level of decision-making (this being the case with avoiding singularities and avoiding mechanical limits in joints). However, very often redundancy is not an advantage but rather a problem that needs resolution. Its implications are particularly emphasized in the well-known inverse kinematics (IK) problem. This is a problem of searching for joint motions that provide a desired trajectory of the end-effector in operational space. The presence of kinematic redundancy means that the same end-effector's trajectory can be executed with different joint motions. Hence,

the problem of the particular choice between available joint motions arises. If there are no specific constraints (like obstacles in workspace) that require the engagement of redundancy, then we have a "useless" surplus of joints and need to find the optimization criterion that will allow for the unique choice. The work done by Potkonjak et al. (2003) explored a typically human redundant task – handwriting, and showed little difference in results obtained by using engineering and biologically-inspired criteria for optimization.

Among optimization criteria which are mainly engineering, we mention the following. Joint movement time is an example of a kinematic cost function. Examples of dynamic cost functions are: quadratic norm of joint control torques (Hollerbach & Suh, 1987), kinetic energy (Khatib, 1983), jerks in joints (Hogan, 1984). Several neuro-physiological and psychophysical cost functions were also suggested (Sief-Naraghi & Winters, 1989): "input energy" was defined as a quadratic norm of input neural signals of motor units (muscles), while "input fatigue" denote the magnitude of such neural signals. The authors suggested some proper combination of these functions, rather than their separate application.

In this study, special attention is paid to functions of joint "discomfort", which were experimentally derived to identify arm postures of maximum comfort (Cruse, et al., 1990). They were determined upon analysis of recorded electromyographic (EMG) signals taken from subjects engaged in experiments, as well as by using their subjective psychophysical evaluations of maximum comfort postures. The fact that a variety of cost functions has already been used to explain principles of human arm motor control indicates that the CNS does not obey any one particular cost function, but also does not violate general physical and technical principles of optimality, from which particular cost functions come about (Latash, 1993). Hence, additional efforts in searching for new appropriate and effective cost functions are justified. They contribute to a better understanding of biological principles of motor control.

When we speak about *comfort* and *discomfort* we certainly have in mind states closely related to some physiological processes, in particular to *fatigue*, but we are still missing the way to mathematically describe these relations.

### Comfort and Fatigue

The underlying idea of the paper has both theoretical and experimental foundations. Practical experience shows that the human arm commonly takes those postures and executes those movements that are the most comfortable. The term "comfortable" relates to joint positions and engagement of motor units and may also be described by the term "pleasant" (a more precise definition will be given later). On the other hand, endurance contractions of motor units cause muscle fatigue, thus introducing an unpleasant feeling, that is, a sense of discomfort. In everyday life it is easy to observe that after a sensation of discomfort caused by muscle fatigue, the human arm normally reduces engagement of the fatigued motor units, by taking postures that require lower participation of these units. This means that while performing repetitive movements requiring continual repetition of motions in operational space (like in screw-driving tasks), the human arm occasionally reconfigures itself by taking a more comfortable posture, rather than proceeding with some particular pose. The ability

to rearrange its motion is enabled by the presence of both actuator and kinematic redundancy in the human arm (Fuentes & Nelson, 1994). Actuator redundancy comes from the possibility to use several motor units for the same motion of any arm joint. Kinematic redundancy results from the existence of seven degrees of freedom (DOFs) in the arm (from shoulder to wrist), which is more than six independent movements required for an arbitrary positioning and orientation of an object in operational space (Potkonjak, et al., 1998; Sciacivco & Siciliano, 1996). Actuator redundancy and its implementation in robotics are challenging problems that deserve attention. However, they are not considered in this paper, although their role in performing movements in biological mechanisms must be pointed out. Instead, this paper focuses on kinematic redundancy and investigates possibilities to distribute the engagement of robot joints in a human-like fashion, imitating the arm's inherent property to execute comfortable motions. The main objective is to achieve a human-like motion. This can be done if an adequate mechanism is established that simulates biological processes of comfort and discomfort in the arm. It would be useful to rely on relevant findings from already published results of theoretical and experimental investigations. A result which is strongly correlated with our work deals with psychophysical cost functions of joint comfort/discomfort and was presented by Cruse et al. (1990). Their validity was practically justified for arm reach posture prediction by Jung et al. (1994). A psychophysical cost function describes an immediate deviation of joint position from the location of maximum comfort. According to experimental findings given by Cruse et al. (1990), the CNS controls arm motion by minimizing the efforts (from a psychophysical point of view) invested during the movements. Physiological and psychophysical investigations indicated that, in the absence of muscle fatigue, a more comfortable joint pose is closer to the middle of the physiological motion range in that joint. Locally minimizing the function describing a deviation from the position of maximum joint comfort, it is possible to determine comfortable motions of a kinematically redundant mechanism.

Mathematical functions representing current distances from middle positions of joints were used in robotics for joint limits avoidance (Liégeois, 1977; Chan & Dubey, 1995). The applied IK method took care of these distances and forced joint motions to the direction opposite to mechanical boundaries. In this paper, such functions are chosen as starting points in the formulation of an analytic procedure for generating joint movements that are equivalent to the movements of a human arm after appearance of discomfort due to muscle fatigue.

Fatigue in humans is a rather complex issue. On one hand, it is a physiological process related to accumulation of metabolic products. This is the aspect that could be, more or less accurately, modeled. On the other hand, fatigue has a psychological aspect – e.g. a fatigued human feels much better if he simply changes the work he is doing – this aspect cannot be modeled and will not be considered in this paper. Physiological sources of fatigue, although extensively studied, are still not thoroughly known. Basically, fatigue appears after long-standing and powerful contractions of muscle motor units. Increase of lactic acid concentration accompanies the progress of fatigue sensation (pH value decrease in muscle

tissue). Simultaneously, the oxygen distribution is reduced, while concentration of some substances particularly influencing the mechanism of muscle contractions and dilatations decreases, e.g., Adenosine Triphosphate (ATP). As a result, muscular activity declines. The progress in a human's feeling of discomfort due to fatigue grows simultaneously with the progress of fatigue itself. The beginning manifestation is like a slight sense of discomfort in a certain part of the arm, then the discomfort transforms into an unpleasant squib which, finally, results in obtuse pain (Öberg, 1994). Additional engagement of other motor units is then required to sustain the necessary arm actuation.

Muscle fatigue can be quantified by means of objective and subjective methods. Objective methods include mechanical, electromagnetic (EMG), metabolic and physiological measurements (Mizrahi, 1997). Another group of methods is based on the subjective evaluation of the sensed fatigue level, given by the subjects participating in experiments (Öberg, 1994). Because there is a variety of factors indicating the current level of fatigue, it is not possible to distinguish an ultimate method for fatigue quantification. The same statement holds for the models of fatigue, available in literature (see, for example, the work by Kiryu (1998)). However, no matter which method is applied for fatigue quantification, it seems reasonable to consider fatigue as an increasing function. That function is often assumed to be exponential (Peckham, 1972; Vodovnik & Rebersek, 1975; Giat, et al., 1996). The slope of the function depends on the actual engagement of motor units and the current level of fatigue. After some time, saturation appears, as a result of reduced activity of exhausted motor units. An example of a diagram with such characteristics is available in (Jenkins & Quigley, 1992) and corresponds to the increase of lactic acid concentration in a muscle engaged in demanding movements.

Keeping in mind the described principal characteristic of the fatigue function, we will suggest for a mathematical non-dimensional variable to be a measure of fatigue in humans. Later, we will explore eventual meaning, sense, and applicability of such variable in robots, introducing "robot fatigue". The temporal characteristic of robot fatigue must be equivalent to the functional characteristic of biological fatigue, thus opening the possibility of generating human-like motions of the robot joints. The aim is to force a redundant anthropomorphic robot arm to track a given end-effector operational space trajectory, along with producing the most comfortable configurations in the sense of the above mentioned psychophysical cost function. Functionally, robot fatigue will have a response equivalent to the biological muscle fatigue, that is, similar dynamic behavior. Results presented in the rest of the paper will justify this approach. An anthropomorphic seven-DOF human/robot arm performing the screw-driving task will be simulated. It will be shown that the robot arm attains postures and executes motions similarly to that of the human arm performing the same task.

## Mathematical Formulation

### Solution of IK Problem

The arm kinematics will be defined in terms of velocities (Nakamura, 1991; Sciavicco & Siciliano, 1996). The relation

between vectors of configuration (joint) velocities  $\dot{\mathbf{q}}$  and operational (end-effector) velocities  $\dot{\mathbf{x}}$ , is given by the Jacobian form

$$\dot{\mathbf{x}} = \mathbf{J}(\mathbf{q})\dot{\mathbf{q}}. \quad (1)$$

We assume that redundancy exists, i.e., the number of operational velocities, denoted by  $m$ , is strictly less than the number of configuration velocities, denoted by  $n$ . Normally, it is  $m = 6$  (three translations plus three rotations). For a human arm it holds that  $n = 7$  (3 degrees of freedom (DOF) in shoulder, 2 in elbow, and 2 in wrist). Dimension of the non-square Jacobian matrix  $\mathbf{J}(\mathbf{q})$  is then  $m \times n$ . The redundancy implies a non-unique IK solution, since a given task, defined in terms of operational velocities, can be accomplished with an infinite number of combinations of configuration velocities. We are interested in those joint velocities that would be executed by a human arm in a given task. Adequate velocities can be found by local minimization of the cost function, formed by two quadratic terms (Sciavicco & Siciliano, 1996):

$$\Omega(\dot{\mathbf{q}}) = 0.5 \dot{\mathbf{q}}^T \mathbf{W}' \dot{\mathbf{q}} + 0.5 (\dot{\mathbf{q}} - \dot{\mathbf{q}}_\alpha)^T \mathbf{W}'' (\dot{\mathbf{q}} - \dot{\mathbf{q}}_\alpha). \quad (2)$$

$\mathbf{W}'$  and  $\mathbf{W}''$  denote  $n \times n$  positive definite symmetric weighting matrices, while  $\dot{\mathbf{q}}_\alpha$  represents an  $n$ -component column vector. The first term in eq. (2) enables us to penalize motion of some joints relative to others. In this paper it should provide a distribution of operational motion to the redundant number of arm joints in accordance with the biologically-inspired concept of distributed positioning (DP) (Potkonjak, 1990; Potkonjak & Krstulovic, 1992<sup>a, b</sup>; Potkonjak, et al., 1998), which means stimulating motions of the joints with low inertia and penalizing motions of the joints with high inertia. It should also enable a proper reconfiguration of the arm, in accordance with the progress of fatigue. The second term in eq. (2) aims at the utilization of kinematic redundancy in the sense of a secondary criterion. Minimization of objective (2) subject to constraint (1) is performed by using the method of Lagrange multipliers (Gottfried & Weisman, 1973). Optimal joint velocities are obtained:

$$\dot{\mathbf{q}} = \mathbf{J}_w^\# \dot{\mathbf{x}} + (\mathbf{I} - \mathbf{J}_w^\# \mathbf{J}) \mathbf{W}^{-1} \mathbf{W}' \dot{\mathbf{q}}_\alpha, \quad (3)$$

where  $\mathbf{W} = \mathbf{W}' + \mathbf{W}''$  and  $\mathbf{J}_w^\#$  denotes the weighted pseudo-inverse of the Jacobian:

$$\mathbf{J}_w^\# = \mathbf{W}^{-1} \mathbf{J}^T (\mathbf{J} \mathbf{W}^{-1} \mathbf{J}^T)^{-1} \quad (4)$$

Vector  $\dot{\mathbf{q}}_\alpha$  enables the local optimization of some secondary objective function  $G(\mathbf{q})$ , used for the proper utilization of kinematic redundancy. Following (Liégeois, 1977),  $\dot{\mathbf{q}}_\alpha$  is defined as the gradient of  $G(\mathbf{q})$ :

$$\dot{\mathbf{q}}_\alpha = -k_a \left( \frac{\partial G(\mathbf{q})}{\partial \mathbf{q}} \right)^T \quad (5)$$

where  $k_a$  is a scalar coefficient. The final form of the IK solution is obtained by substituting (5) into (3):

$$\dot{\mathbf{q}} = \mathbf{J}_w^\# \dot{\mathbf{x}} - k_a (\mathbf{I} - \mathbf{J}_w^\# \mathbf{J}) \mathbf{W}^{-1} \mathbf{W}' \left( \frac{\partial G(\mathbf{q})}{\partial \mathbf{q}} \right)^T \quad (6)$$

### Choise of the Secondary Objective Function

Definition of the secondary objective function  $G(\mathbf{q})$  providing comfortable motion is discussed in this subsection. The distances of current joint positions  $q_i$ ,  $i=1, \dots, n$ , from the mechanical joint limits  $q_{i,\min}$  and  $q_{i,\max}$  will be the basis for definition of the secondary objective function. In the previous section it was already pointed out that the middle values of human arm joint ranges coincide with positions of the maximum comfort. This fact justifies the choice of  $G(\mathbf{q})$  as a function penalizing deviation from the middle values (Liégeois, 1977; Chan & Dubey, 1995):

$$G(\mathbf{q}) = \frac{1}{2n} \sum_{i=1}^n \left( \frac{q_i - \bar{q}_i}{q_{i,\max} - q_{i,\min}} \right)^2, \quad \bar{q}_i = \frac{q_{i,\max} + q_{i,\min}}{2} \quad (7)$$

or

$$G(\mathbf{q}) = \sum_{i=1}^n \frac{1}{4} \frac{(q_{i,\max} - q_{i,\min})^2}{(q_{i,\max} - q_i)(q_i - q_{i,\min})} \quad (8)$$

### Model of Arm Dynamics

The dynamics of the arm plays an important role in establishing a procedure that provides human-like motions of joints. We adopt the standard representation of arm dynamics:

$$\mathbf{H}(\mathbf{q})\ddot{\mathbf{q}} + \mathbf{h}(\mathbf{q}, \dot{\mathbf{q}}) = \boldsymbol{\tau} + \mathbf{J}^T \mathbf{F} \quad (9)$$

where  $\mathbf{q}$ ,  $\dot{\mathbf{q}}$ , and  $\ddot{\mathbf{q}}$  denote  $n \times 1$  vectors of joint positions, velocities, and accelerations;  $\mathbf{H}$  is an  $n \times n$  inertia matrix;  $\mathbf{h}$  is an  $n \times 1$  vector of centripetal, Coriolis', friction and gravitational torques;  $\boldsymbol{\tau}$  denotes the  $n \times 1$  vector of driving torques in the joints;  $\mathbf{J}$  is the Jacobian, and  $\mathbf{F}$  is the  $m$ -component external force/torque. Driving torques are produced by actuators – muscles in humans and motors in robots.

### Model of Fatigue Process

This subsection suggests a method that should be used to simulate the effects of physiological fatigue in human muscles.

The key features of the fatigue function were revealed in subsection “*Comfort and Fatigue*”. We now look for a proper mathematical model to express these features. We first introduce a non-dimensional variable being the measure of fatigue. It will be called simply *fatigue*. Let  $z_i$  be the fatigue in joint  $i$  ( $i=1, \dots, n$ ). We assume that the level of fatigue directly depends on the accumulation of metabolic products – concentration of lactic acid. So, the concentration could be considered as fatigue, after normalizing it to become a non-dimensional variable.

We consider fatigue as an accumulation process. Like in modeling any accumulation process, we will consider the gradient of the state coordinate as balancing input and output. A good paragon is the process of heating a body, being the accumulation of thermal energy: temperature  $\theta$  is the state variable,  $R\dot{\theta}$  is the input from electric heater,  $k(\theta - \theta_0)$  is the output (energy transition body-to-ambient), and the model is finally  $C\dot{\theta} = R\dot{\theta} - k(\theta - \theta_0)$ , where  $C$  is the specific thermal capacity. With the fatigue process,  $z_i$  is the state variable. Let us discuss the input and the output.

- One notes that there exists an input, a source of lactic acid – these are metabolic processes which intensify with the stronger muscle activity i.e. with the higher joint torque  $\tau_i$ . There are no reliable results revealing how the production of acid depends on the torque  $\tau_i$ . In order to develop the methodology, we follow the paragon and adopt a quadratic function. So, the input rate can be expressed as  $A_i \tau_i^2$ , where  $A_i$  is the coefficient that should be determined experimentally.

- Next, one notes that there is also an output – blood takes the acid out of the muscle. The output rate can be considered proportional to the difference in concentration between the muscle ( $z_i$ ) and the blood ( $z_{i,0}$ ), and so it is:  $K_i(z_i - z_{i,0})$ , where  $K_i$  is the conductance (transition coefficient).

Now the balance is:

$$M_i \dot{z}_i = A_i \tau_i^2 - K_i(z_i - z_{i,0}) \quad (10)$$

where  $M_i$  is the specific accumulation capacity. The model can be rewritten to the form

$$T_i \dot{z}_i = \frac{A_i}{K_i} \tau_i^2 - (z_i - z_{i,0}) \quad (11)$$

revealing the time constant  $T_i$ .

Model (11) considers  $z_{i,0}$  as being constant. This means that we neglect the accumulation process in the blood. If one wishes to expend the fatigue dynamics to include bloodstream system, he should note that the acid taken from the muscle should be treated as input to the blood. The output should be defined as the place where the “cargo” is unloaded (liver). The concentration  $z_{i,0}$  now becomes a new state variable and the fatigue process becomes of the second order.

### The Full Model

The full model means the set of equations that can be numerically integrated to calculate the system behavior in all its aspects. So, we talk about simulation and it goes in few steps:

- We start from the fact that a given task means a prescribed motion in operational space,  $\mathbf{x}(t)$ .
- IK is resolved by applying expression (6) along with (8). This way, the joint-space motion  $\mathbf{q}(t)$  is obtained which satisfies the request for comfort.
- With known joint motions, the joint torques  $\boldsymbol{\tau}(t)$  are found from the dynamic model (9).
- Finally, the progress of fatigue  $\mathbf{z}(t)$  is calculated by integrating the model (11).

What still remains an open question is: does and how fatigue influences the above formulated simulation procedure.

### How Fatigue Influences the Arm Motion

Here, we suggest the proper means for establishing the functional dependence between fatigue time history  $z_i(t)$ ,  $i = 1, \dots, n$ , and robot arm motions. For this purpose, we should reinstate the expected effects of fatigue progress. During manipulation, a human arm performs movements adequate to the desired manipulation task, permanently accommodating its configurations to the actual level of muscle fatigue. Present kinematic and actuator redundancy allows execution of the

manipulation task in a comfortable way, by appropriate distribution of joint motions and participation of different motor units. In such ways exhausted muscles may recover and other muscles increase their activity. A similar strategy could be applied to a robotic arm. Note that capabilities of the kinematic redundancy will be utilized only – actuator redundancy is out of scope of this paper.

### Reconfiguration

For each arm joint it is necessary to specify an appropriate critical level of the fatigue:  $z_{i,cr}$ . It is the level when a human starts to feel unpleasant sensations in the considered joint. Thus,  $z_{i,cr}$  should not be seen as a definite limit but rather a bound of a desired region of working mode. If the fatigue  $z_i$  is less than  $z_{i,cr}$ , a human feels fine and will continue working in the same way. If  $z_i$  exceeds the critical value, the human can still work in the same way but he will not feel comfortable. To prevent the discomfort, a proper depression of motion in the critical joint is needed. It is necessary to reconfigure the arm by taking a posture that will engage other joints more thus giving the exhausted joint a chance to rest. Note that reconfiguration is done in the joint space and does not affect the operational motion  $\mathbf{x}(t)$  and the execution of a given task. Reconfiguration of joint motions can be achieved on the IK level, by means of the proper weighting matrices. We remind that there are two matrices making a sum  $\mathbf{W} = \mathbf{W}' + \mathbf{W}''$ . Matrix  $\mathbf{W}'$  should provide human-like distribution of joints motions (DP concept) and an adequate reconfiguration of the arm with respect to actual levels of joint fatigue. By means of  $\mathbf{W}''$  one can specify higher engagement of some joints in realization of the secondary objective. In this paper, it is assumed that all joints have equal priority in realization of the secondary objective. In such a way, the role of  $\mathbf{W}'$  determines a particular choice of  $\mathbf{W}$ . To ensure the proper reconfiguration, penalty functions are introduced into the weighing matrix:

$$\mathbf{W} = \text{diag}[\varphi_1(z_1), \dots, \varphi_n(z_n)] \quad (12)$$

Penalty functions  $\varphi_i(z_i)$  should penalize the exhausted joints and stimulates those that are still “fresh”. Mathematically speaking,  $\varphi_i(z_i)$  should be constant until  $z_i$  reaches  $z_{i,cr}$  and monotonically increasing above  $z_{i,cr}$ . In this way, the penalty functions will contribute to reduced movement of each joint in which the actual value of fatigue exceeds an assigned critical level. The choice of a particular penalty function is task dependent. For the simulation study of this article we adopt a quadratic function:

$$\varphi_i(z_i) = \begin{cases} w_i, & z_i < z_{i,cr} \\ w_i + k_i(z_i - z_{i,cr})^2, & z_i \geq z_{i,cr} \end{cases}, \quad (13)$$

where the initial weighing factor  $w_i$  is a scalar constant and the coefficient  $k_i > 0$  determines the desired slope of the penalty function.

It is expected that reduced engagement of the exhausted joints will give them a chance to rest and go out of the critical working mode. Several reconfigurations may happen, one after the other, as different joints reach the critical levels. If the imposed task is not too tough, the arm will finally finds a

steady state in which it can operate for a longer time. We remind that reconfigurations do not affect the execution of the task since it does not reflect in the operational space  $\mathbf{x}$ .

### Degeneration

If the task is too demanding, it may happen that, in spite of reconfiguration, the fatigue functions  $z_i(t)$  continue to rise. This means that reconfiguration delays the fatigue problem but does not eliminate it. To handle this situation, some upper limits of fatigue are adopted:  $z_{i,max}$ ,  $i = 1, \dots, n$ . The limit in the  $i$ -th joint,  $z_{i,max}$ , determines the level when discomfort in the joint turns into pain that cannot be endured. In this situation, a further rise of fatigue must be prevented regardless of the consequences, even if the execution of the task is compromised. Hence, we call this phase degeneration. The over-exhausted joint must rest and we emulate this process by using a “torque limiter”. The limiter will allow the torque that is smaller than the required value by the factor  $D$ , and thus for the joint  $i$  it will be:

$$\tau_i = D_i(z_i)\tau_i^{req} \quad (14)$$

where  $\tau_i$  is the actual torque and  $\tau_i^{req}$  is the value required by the dynamics of the given task. The damping factor  $D_i(z_i)$  depends on the actual level of fatigue. In order to efficiently relax the over-exhausted joint, an exponentially decreasing function is adopted:

$$D_i(z_i) = \begin{cases} 1, & z_i \leq z_{i,max} \\ e^{-(z_i - z_{i,max})}, & z_i > z_{i,max} \end{cases} \quad (15)$$

Damping the torque will result in insufficient joint drive and accordingly in the degeneration of motion trajectories, in both joint ( $\mathbf{q}$ ) and operational ( $\mathbf{x}$ ) space. Thus, the task is no more executed properly.

### Implications to a Robotic Arm

The above discussion was mainly focused on human arm but with the idea in the background to find a proper interpretation and implication in robots. The answer is generally in the possibility to achieve a human-like behavior of robot. Potkonjak et al. (2002<sup>a, b</sup>, 2005) suggested approaching this problem from the aspect of human-robot communication, and contributing to gestural communication. The research paid particular attention to generation of a nonverbal message about overloading. The thermal dynamics, that is, robot motors heating, was considered and the rise of temperatures was used as the measure of “robot fatigue”. Redistribution of joint engagements was suggested as the solution which would relax the overheated motors. This reconfiguration would be observable to people being around and thus would be a nonverbal message about fatigue and exhaustion. The authors mainly concentrated on robots engaged in fine-motor-control tasks and particularly handwriting. The present research shares some basic ideas but it generalizes the problem by putting it in a wider context of mathematical modeling of physiological processes and human-robot analogy.

## Example – Screw-Driving Task

Effects of the suggested method are analyzed for a task very demanding regarding applied force and torque – the screw-driving task. A human and/or an anthropomorphic robot arm has to screw the bolt into the hole on the vertical work surface (wall). Although this operation often involves a specific motorized tool, an electric screw-driver, we here consider screw-driving as a purely manual operation. This means that, apart from enabling the proper position of the “old-fashion” screwdriver in the space, the arm should also provide angular screw-driving movements about the longitudinal screwdriver’s axis (Fig. 1).

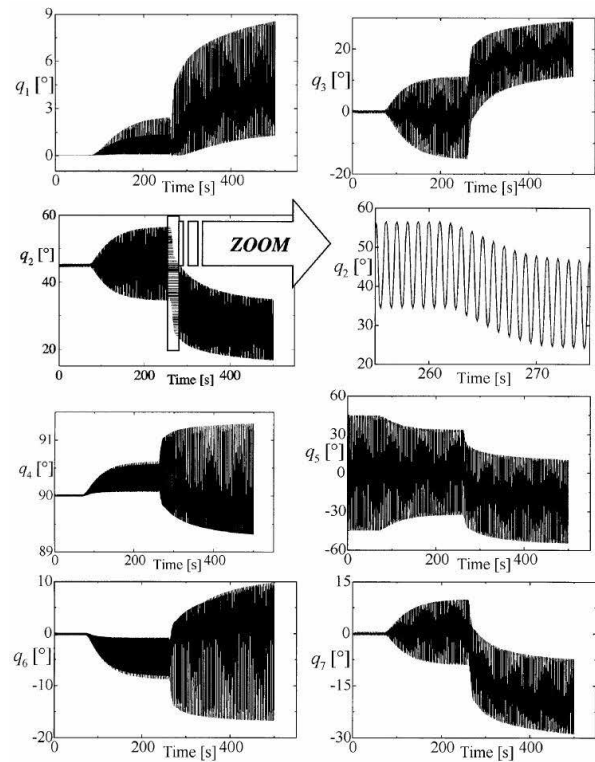

**Fig. 1.** Redundant arm in screw-driving task: (a) configuration, (b) initial position

The considered arm configuration is shown in Fig. 1a. It has seven DOFs, meaning that it is redundant for the given task that requires six. Initial position is shown in Fig. 1b.

Initial position of the robot arm is defined by:  $q(t=0) = (0, 45^\circ, 0, 90^\circ, -45^\circ, 0, 0)$ . Accordingly, the initial arm posture has a stretched wrist and the forearm and the screwdriver are aligned perpendicularly to the wall.

A screw-driving task requires rotational motion of a screw about its longitudinal axes, along with keeping its

perpendicularity to the wall. It is assumed that screwing consists of a series of single revolute movements (forward and backward), each of  $\pi/2$  [rad]. A forward rotation (screwing in) is indicated in Fig. 1. Backward rotation does not drive the screw, but only prepares the screwdriver for the next turn. Each movement takes  $T=0.5$ s. Different studies investigating motor control of human movements have shown that human arm performs smooth voluntary movements with bell-shaped velocity profiles (for illustration, see (Hogan, 1984)). In our simulations the bell-shaped velocity profile was approximated with a cosine velocity profile (Vukobratovic & Kircanski, 1986) and applied to rotational motions of the screwdriver. This way we complete the definition of the end-effector motion task. The full task, however, includes the force and the torque which the screwdriver applies to the screw – the arm motor units have to provide longitudinal force  $F=50$ N, and the torque  $M=6$ Nm about the longitudinal axis. The force and the torque are applied only while turning the screwdriver forward – the backward rotation is relaxed.

**Fig. 2.** Joint motions:  $q_i(t)$ ,  $t = 1, \dots, 7$ . Zoomed view of  $q_2$  shows the motion drift in shoulder: upper arm starts to move down toward the trunk.

We now apply the derived models of fatigue progress and the suggested method for IK resolution, with the aim to simulate the arm behavior in the imposed task. The calculated behavior will then be compared with the behavior observed with a control group of 5 human study subjects. Note that the model parameters used in simulation were tuned (using simulation experiments) so as to stimulate the system to feature relevant effects earlier, thus eliminating the need for too long simulation. Hence, the parameters used in simulation

differ from those of study subjects. Monitoring of the control group was not based on some measurement but rather on the visual observation and the verbal descriptions given by the study subjects. Therefore, the simulation results and the experiment can be compared on the qualitative level only.

The joint motions,  $q_i(t), t = 1, \dots, 7$ , obtained by simulation are shown in Fig. 2 (note that the applied order 1, 3, 2, ... instead of regular 1, 2, 3, ... uses the space in the figure more economically). Note that the total time of monitoring the event was 500 s. Since a cycle of screwing-in (forward-plus-backward rotation) lasts 1 s, it is not possible to observe a particular oscillation in joint motions. One can only see the envelope, but it is sufficient for understanding the results. The only exception is the zoomed diagram for joint 2, where oscillations are visible. Bearing in mind the arm starting position, it is clear why the screw driving is initially performed by joint 5 alone. It is the only joint able to provide the rotational motions about the longitudinal axis of the screwdriver.

The simulated progress of fatigue,  $z_i(t), i = 1, \dots, 7$ , is presented in Fig. 3.

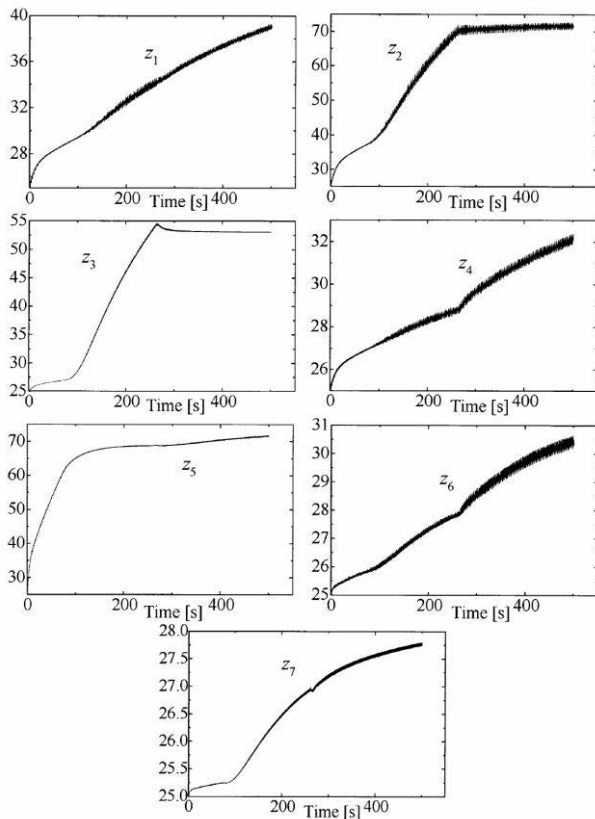

Fig. 3. Progress of fatigue,  $z_i(t), t = 1, \dots, 7$ .

Relations between time histories of  $q_i(t)$  and  $z_i(t)$  should be considered next. This will be done by comparing diagrams from Figs. 2 and 3. Let us start from joint 5. Diagram  $q_5$  in Fig. 2 shows large turns which generate the screwing torque. Hence, fatigue  $z_5$  (Fig. 3) progresses fast. When  $z_5(t)$  reaches the assigned critical level  $z_{5,cr} = 60$ , penalty function  $\varphi_5(z_5)$

starts to work, causing reduced engagement reflecting in decreased amplitude of motion in diagram  $q_5(t)$  (Fig. 2).  $z_5$  features a reduction of slope. The change in slope is not sharp, but comes some time after reaching  $z_{5,cr}$ , resembling human reaction. So, with appearance of fatigue symptoms in the joint 5, its engagement decreases. This is enabled by proper participation of other joints, which starts exactly at the moment when joint 5 reaches its critical value. This effect is apparent from all diagrams  $q_i(t)$ .

Diagrams of motions in joints 2, 3, and 7 deserve special attention, because of their prevalent participation in compensating the reduced involvement of joint 5. This is also similar to the natural behavior of human arm, which after sensing the discomfort (fatigue) in the forearm, engages exactly the same joints to relax exhausted muscles. Increased engagement of these joints results in increase of their fatigue. Two of the three most actively participating joints (2 and 3) are in the shoulder. These joints, besides other roles, compensate the gravity load of the complete arm. The third active rotation (joint 7) is in the wrist and it coincides with that rotation of a human wrist which is able to participate in endurance movements. Joint 7 can stand significant dynamical demands and slowly fatigues. Its engagement in providing speeded-up motions in the writing task has been investigated in (Potkonjak, et.al, 1998). These facts imply that fatigue effects should appear in the shoulder first, rather than in the wrist. This is equivalent to the natural behavior of a human arm. As a consequence, fatigue  $z_2$  is the next (after  $z_5$ ) to reach its adopted threshold  $z_{2,cr} = 70$ . After reaching the threshold, the penalty function will keep the fatigue in the vicinity of that level. The motion in joint 2 (shoulder) drifts toward lower values of  $q_2$ . This is shown in Fig. 2 and zoomed for better observation. The suggested method for redundancy resolution based on actual fatigue provides reconfiguration of the arm mechanism in a way identical to a human arm after appearance of biological fatigue. The arm puts its elbow closer to the trunk, after subject to fatigue caused by endurance movements during screw driving. This new posture of a human arm is more comfortable to work. It is important to note that the arm proceeds its normal operation (in the sense of task execution), just taking the new posture. Redistribution of motion, depression of some joint motions and stronger engagement of others, does not compromise the end-effector motion. The complete redistribution is shown in diagrams  $q_i(t), t = 1, \dots, 7$  (Fig. 2).

In the above discussion, the statements that some behavior calculated by simulation resembled the human behavior, were based on the qualitative comparison between the simulation results and the observation from the human control group. The most visible reaction of human study subjects was turning the elbow down to the trunk. This is also visible in the simulation diagram of  $q_2$  in Fig. 2.

## Conclusion

The objective of the paper was to explore how physiological processes, in particular fatigue, influence human motion, with the idea of formulating mathematical models describing this relation. Resolution of the inverse kinematics of redundant

arm was discussed first, proposing a biologically inspired method that took care of the comfort of motion and utilized the actual level of fatigue in arm motor units. The method allowed the reconfiguration of the arm that gave the fatigued joints a chance to rest by engaging more the joints which were “fresher”. In order to simulate the progress of fatigue, mathematical model of fatigue was derived based on a general model of accumulation processes. The developed methods were tested by simulation and qualitative comparison with the observed behavior of the human control group. Results obtained by simulation featured a human-like behavior that qualitatively agreed with the observation from study subjects. Implications of the results to anthropomorphic robots were indicated.

## Abstract

Biological multicellular structures can not only self-generate from a single cell but also self-regenerate after damage. In this paper we investigate self-regeneration in a model of artificial development, Epigenetic Tracking. 3-dimensional cellular structures grown using our model reach a size and a level of complexity unmatched by other models in the field, thanks to several features of Epigenetic Tracking. One of these features is that only a small fraction of cells in the body, called drivers, orchestrate development. In this paper we use the mechanism for the generation of drivers based on the diffusion of morphogens as a foundation of several new mechanisms in Epigenetic Tracking, and show that these mechanisms allow for self-regeneration after removal of arbitrarily large portions of the multicellular body.

## Introduction

Models of development can be divided into two broad classes: grammatical and chemical. The first class includes L-systems, introduced by Lindenmayer (10) to model plant growth, and models based on context-free or context-sensitive grammars, instruction trees or directed graphs (e.g., 1; 7; 8). Grammatical models can generate surprisingly complex, life-like shapes, even though they do not include mechanisms corresponding to the biological processes working at the molecular level. In contrast, chemical models (e.g., 2; 9; 11) do include such mechanisms, inspired by information processing inside cells (gene regulatory networks) and by communication between cells (diffusion of chemical substances; considered already by Alan Turing, 1952). Although some models of development can be considered either grammatical or chemical, the division between these classes is fuzzy, and much can be achieved by combining features of both to bring computational efficiency on one hand, and biological plausibility on the other. Such combination of features stands behind Epigenetic Tracking (3).

In Epigenetic Tracking, self-generation of 3-dimensional multicellular structures starts from a single cell containing a genome that encodes all the information necessary to direct development. The genome can be evolved using a genetic algorithm with a fitness function measuring the proximity of

the final structure (the body) to a target shape. The complexity of the bodies obtained with Epigenetic Tracking (number of fine morphological features and patterning) and their size (reaching millions of cells) has not been matched yet by any other model. Self-generation of such large and complex bodies is possible thanks to the division of cells into normal cells and drivers: a small fraction of cells that orchestrate development.

We have recently introduced a new mechanism into Epigenetic Tracking, a mechanism for the generation of drivers, based on the diffusion of chemical substances (morphogens; 6). In the present paper we introduce several additional new mechanisms, guided by the assumption that regeneration replays the events that occurred during development (13, see also 2). We show that these additional mechanisms allow to add self-repair to the list of phenomena we previously investigated in our system (ageing and cancer, 4; and the hypothetical transfer of information between somatic cells and the germline, 5; Fontana and Wróbel).

## Epigenetic Tracking: a model of evolving, self-generating multicellular structures

In Epigenetic Tracking multicellular bodies consist of cube-shaped cells on a 3-dimensional grid. The growth starts from a single cell and continues through a pre-specified number of developmental stages. Cells belong to two categories: *normal* and *drivers*. Each driver has an associated array of digits, called *mobile code*. All the cells carry the same genome, an array of characters (from a 4-letter alphabet). The mobile code can be considered as an abstraction for the set of regulatory factors present in a cell: it allows drivers to behave differently despite sharing the same genome.

The genome consists of developmental genes, which all have a left part and a right part. The left part contains three fields: *switch*, which specifies if a gene is active or inactive, *timer*, and *mobile sequence*. At each developmental stage, the mobile sequence of each developmental gene is compared with the mobile code value of each driver, and the timer is compared with the value of the current developmental stage. If both match, the right part of the gene fires. Each

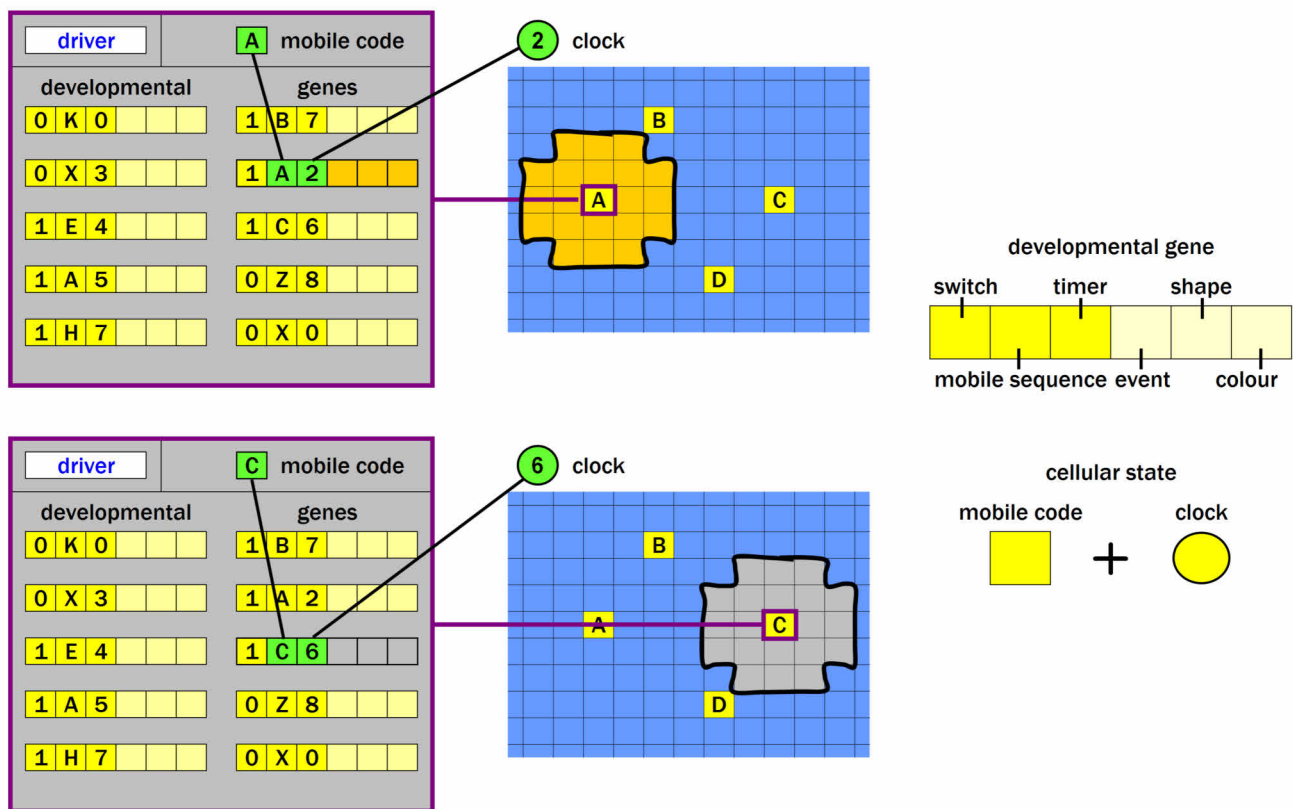

Figure 1: Orchestration of developmental events by drivers in Epigenetic Tracking. On the top, a driver (one of the cells in yellow) with mobile code A triggers a proliferation event at developmental stage 2. On the bottom, a driver with mobile code C triggers a cell death event at stage 6. Black lines indicate the match of the fields in the left part of the genes with the mobile codes of the drivers and the clock. The shape of the created or deleted cell masses is encoded in the right parts of genes. The schematic genome has 10 genes.

right part has three fields. One field determines the type of event – local proliferation or death (removal of cells from the grid; Fig. 1). Another field specifies the shape of the local structure created by proliferation or removed by cell death. The third field determines the phenotype of the normal cells produced in case of proliferation (which is represented by their colour).

A proliferation produces normal cells and drivers. Drivers are placed among normal cells after proliferation, and are much fewer than normal cells in number. Each new driver obtains a new and unique mobile code. The creation of drivers in the experiments described in this paper relies on the diffusion of morphogens, belonging to a finite number of types (we recently implemented this mechanism in Epigenetic Tracking, 6). After a driver orchestrates a developmental event, it persists in the structure and becomes a source of the morphogen which had the lowest concentration at the driver's position when this cell was activated; the diffusion of this morphogen will contribute to the chemical landscape in the body and influence the creation of future

drivers (Fig. 2).

The concentration of a particular morphogen ( $C$ ) in the body follows the equation  $C = 9 - \text{round}(D/G)$ , where  $D$  is the Euclidean distance between a given position on the grid and the closest driver that produces the morphogen, and  $G$  is a system parameter. If the formula gives a negative number, the concentration is set to 0. Because of the rounding, the concentrations can take an integer value between 0 and 9, and positions close-by can have the same concentrations of all morphogens. The cell in the centre of each such region (determined by averaging the coordinates of all the cells there) is a candidate for becoming a new driver. The drivers are created after sorting the regions by size, in the largest region first, provided that each new driver is sufficiently far away from the closest existing driver (this distance is also a system parameter).

The mobile code of the new drivers is derived from the code of the driver that created it through proliferation, but also includes information about the concentration of morphogens in the region. To do so, the mobile code is sep-

Figure 2: Generation of new drivers based on diffusion of morphogens. Driver cells which have orchestrated an event (yellow cells circled in top panel) persist after doing so in the structure and produce morphogens. There is a finite number of morphogens and their concentrations are rounded, so the structure divides up into multicellular regions (each marked with a different colour in the bottom panel) having the same concentrations of morphogens. New drivers (indicated with red circles) form from the central cells in such regions, if these cells are sufficiently distant from any other driver.

arated into as many sub-fields as there are developmental stages, and the concentrations are encoded in the sub-field corresponding to the current stage. For example, if the concentration values are [4,7,8,2], the number encoded in this sub-field (using a 4-digit positional code) will be 4782. The parameters of the system can be varied to ensure a sufficiently high driver density as to preserve evolvability (6).

Because the first proliferation originates from one initial driver cell (the zygote), morphogen regions are absent, and another mechanism is needed at this point to form new drivers: they are placed using a pre-specified pattern. This initial placement of drivers can be seen as deriving from morphogen gradients in the egg itself (maternal factors, 13).

#### Four new mechanisms in Epigenetic Tracking to allow for self-regeneration

Because of the central assumption of our model of regeneration (that the state of the body at the start of regeneration has

Figure 3: Dependencies among drivers. The cells turned into drivers are originally produced in proliferations orchestrated by other drivers (these dependencies are represented by black lines on the top panel), but their formation is influenced by morphogens produced by other drivers (blue lines), with the exception of drivers created in the first stage (which are not created using morphogens; see text for details). This information can be used to outline a dependency graph (bottom panel) between drivers which were activated during development (shown in green), and can be reactivated for regeneration. For example driver E depends on driver cells B, and A.

to be similar to some state during embryonic development), the drivers that orchestrated development need to persist in the body – they will be needed to orchestrate the events during regeneration. These drivers, once they trigger a developmental event, are kept in a deactivated state (so that this event is not triggered again). This is the first new mechanism introduced in our system.

The second mechanism permits detection of damage. All cells created in a proliferation event send chemical signals to the deactivated driver which created them. If many of these cells are destroyed, this driver can be reactivated because it receives less of these signals. A large damage can result in the reactivation of many drivers.

Before such reactivation can occur, however, the debris left by the damage needs to be removed, so that the structure contains no cells created during development by the driver that is reactivated, or indeed any cells whose creation depended on such a driver (using a dependency graph like

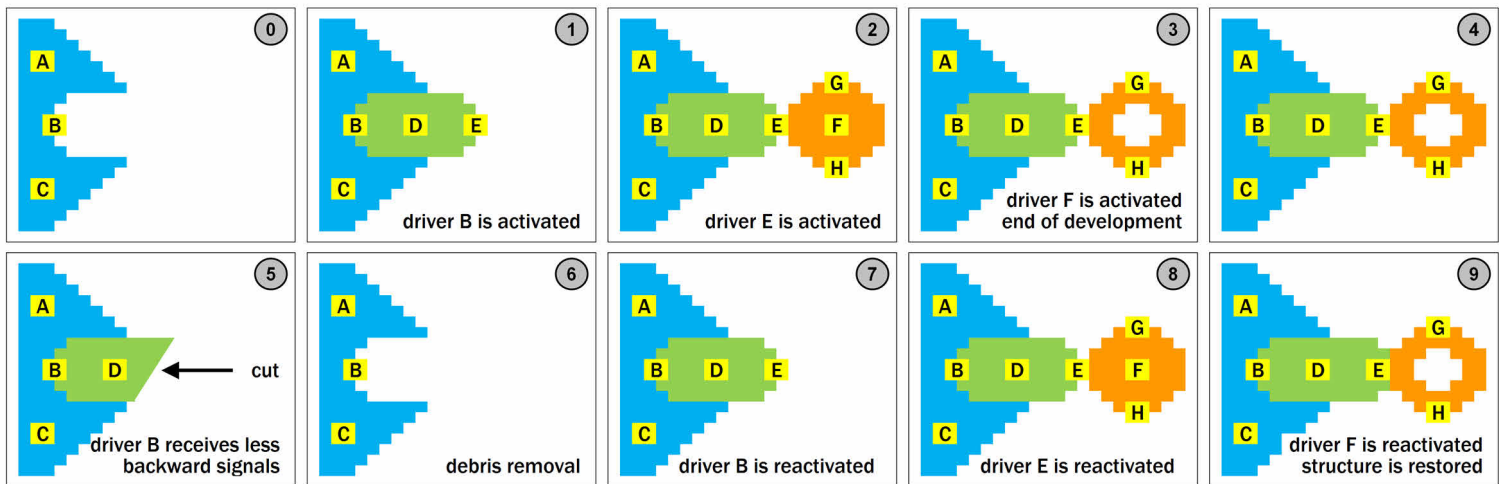

Figure 4: Regeneration of a body part. Panels (and stages) 0-4: the developmental trajectory for a hypothetical body part. After the end of development (stage 4), a portion of the structure is cut at stage 5. After debris removal (stage 6), driver B is reactivated, leading to the recreation of drivers E, which is also reactivated, and so on, until the structure is completely regrown.

the one in Fig. 3). Should such cells remain, some parts of the structure could be duplicated or regeneration would not work correctly. This debris removal is the third new mechanism.

The fourth mechanism recreates exactly the same landscape of morphogens as during development, by excluding from the sources of morphogens all the drivers activated originally (during development) after the driver that is now reactivated during regeneration. For example, if the reactivated driver was originally activated at stage 5, a driver activated at stage 12 would be excluded.

Finally, we needed to deactivate one of the mechanisms that were present in previous versions of Epigenetic Tracking: in the version presented here, proliferation does not cause the cells present at this point in the structure to be pushed away, neither during development nor during regeneration (otherwise the morphogen landscape would not be recreated). When a proliferation is triggered by a driver embedded in the existing structure, the new cells are placed in the grid only if the relevant positions are free, so that no old cell is deleted. The proposed mechanisms ensure that the drivers activated to produce a given body part during development are reactivated during regeneration, leading to the same sequence of events (Fig. 4).

### Results and Discussion: Self-generation and self-regeneration of multicellular structures in Epigenetic Tracking

We have run 10 independent simulations of evolution using a genetic algorithm, with constant population size (124 individuals). At the first generation, all genomes were random. At each subsequent generation the genomes of

the individuals in the new population were created as follows: (i) the genomes for the 16 best individual in the previous population were copied from the new population without change (elitism); (ii) 96 genomes were inherited from the previous population with selection probability proportional to each individual's fitness, crossover (one point, with 50% probability) and mutation (the rate is 0.005 per character in the genome); (iii) 12 genomes were created completely randomly. This influx of random genomes introduces new genes into the population to increase evolvability. Another measure to increase evolvability in Epigenetic Tracking, called germline penetration, creates genes with mobile sequences that match mobile codes in the driver cells which have not been activated during development, and inserts them into the genome of next generation's individuals (see Fontana and Wróbel, for the discussion of the biological motivation for this mechanism).

The fitness function rewarded the proximity of the adult structure (the structure after 12 developmental stages) to the shape of a lizard, requiring about 500 000 cells. Each simulation was run for 40 000 generations, and in all simulations the best individual was very close to the target (Fig. 5; only two champions representative for 10 are shown; all the champions had genomes with 80-100 developmental genes). Then, portions of the final structure were removed and allowed to regenerate (Fig. 5) following the debris removal. We performed tens of such experiments, with different damages for different champions, and in all simulations the regeneration was perfect.

Our model of regeneration draws the inspiration from the amazing properties displayed by many biological organisms. The regenerative capabilities in the living world occupy a

Figure 5: Self-generation and self-regeneration of multicellular structures consisting of hundreds of thousands of cells: the main contribution of this paper. Two champions of independent evolutionary runs are shown in two separate panels, each with 24 frames. In both cases, development unfolds from a single cell (circles) in 12 developmental stages (frames 1-12). After stage 12, the four limbs (top panel) or the tail and the head (bottom panel) are cut off (arrows). After the debris is removed, the structures are completely regenerated.

wide spectrum, ranging from limited cell renewal within tissues, to full regeneration of entire multicellular organisms starting from small fragments. The results obtained in this paper correspond to the latter, most complex extreme of this spectrum, perhaps raising doubts about the biological plausibility of the mechanisms we proposed.

We have built our model of regeneration on two foundations: (i) drivers who were active during development persist, deactivated, in their original positions at later stages of life; (ii) morphogens released from drivers created during later development stages than the damaged part are excluded during regeneration. Both foundations are required to recreate the same conditions during regeneration as the conditions during development in order to guarantee perfect regrowth after damage. A less perfect regrowth – more common in nature – will result, we suspect, if the mechanisms we introduced in Epigenetic Tracking do not work perfectly. We predict that then the regeneration will work better for more elongated parts of the structure (such as limbs or a tail), corresponding to more “isolated” driver subsets, i.e. with less dependencies on subsets in other body parts. More central body parts (e.g., the trunk) correspond to driver subsets with more dependencies, so they require a profound debris removal. We plan to investigate in our future work if these intuitions agree with simulation results for imperfect mechanisms in Epigenetic Tracking.

Are both foundations described above biologically plausible? Drivers in Epigenetic Tracking are inspired by biological embryonic stem cells (Fontana and Wróbel). Embryonic stem cells are totipotent cells, able to differentiate into all cellular types, while adult stem cells are pluripotent cells persisting throughout life, dividing when there is a need to replenish died cells or to regenerate damaged tissues. So persisting quiescent drivers in Epigenetic Tracking can be compared to adult stem cells. On the other hand, perfect debris removal and recreation of the chemical landscape present during development is not entirely plausible, and the fact that it is not may explain why biological organisms with high complexity have a limited ability to regenerate whole parts of their body. Regardless of the degree of biological plausibility, the mechanisms we introduced for simulated development in Epigenetic Tracking could be implemented in artificial physical systems, provided that physical building-blocks able to store genetic information are available.

## Conclusions

Our model of multicellular development, Epigenetic Tracking, allows to self-generate 3-dimensional structures consisting of millions of cells, structures with shapes that have a level of detail unmatched by other models of artificial development. We presented in this paper a new version of Epigenetic Tracking, in which the drivers – cells that correspond to biological organisms, fewer in number than other cells

in the structure – are created using diffusing morphogens, persist through life, and can orchestrate regrowth after damage. The presence of the new mechanisms in the model did not impair evolvability, and allowed for perfect regeneration after damage. We plan to investigate in future work if the regeneration will be less perfect – like in highly complex biological organisms – if these mechanism do not work perfectly. These future work will aim to infer general rules for regeneration in biological and artificial systems.

## Abstract

This paper investigates the dynamics of decentralised nest construction in the ant species *Leptothorax tuberointerruptus*, exploring the contribution of, and interaction between, a pheromone building template and a physical building template (the bodies of the ants themselves). We present a continuous-space model of ant behaviour capable of generating ant-like nest structures, the integrity and shapes of which are non-trivially determined by choice of parameters and the building template(s) employed. We go on to demonstrate that the same behavioural algorithm is capable of generating a somewhat wider range of architectural forms, and discuss its limitations and potential extensions.

## Introduction

When building their nests, insect colonies are capable of creating extremely complex structures without employing explicit blueprints (Theraulaz et al., 1998). Such feats of collective construction are achieved via stigmergy, where deposition of building material and pheromones attract, guide and stimulate other nest mates. For example, some ant species progressively encircle their brood with a wall constructed from collected stones (Franks et al., 1992), while paper wasps build structured combs that are sometimes protected by an external envelope (Jeanne and Bouwma, 2002), and termites are capable of building highly complex nests with ventilation shafts, galleries, brood chambers, fungus gardens and royal chambers (Bonabeau et al., 1998; Ladley and Bullock, 2004, 2005).

Due to the inherent parallelism and stochasticity of self-organisation, insect nest construction is prone to problems of interference and needless redundancies are often created (Di Marzo Serugendo et al., 2011). Nevertheless, the fact that the individuals themselves only require limited sensors, memory and reasoning (Mason, 2002) makes attempting to reproduce their behaviour in robots attractive (Holland and Melhuish, 1999; Parker and Zhang, 2006; Bullock et al., 2012). In the future, we might be able to rely on swarms of extremely simple and cheap robots to autonomously build structures guided by environmental cues. For example, we could place signal beacons to suggest where corners of a

building should be or where space should be created for windows and doors.

However, in order to be able to control insect-like construction, we must first understand it. This paper investigates nest building by the ant *Leptothorax tuberointerruptus*, which creates circular structures with one or more entrances around its brood. These nests are created inside flat horizontal cavities and can thus be studied in two dimensions (Franks et al., 1992; Franks and Deneubourg, 1997; Theraulaz et al., 2003). Ant builders can be divided into ‘internal’ and ‘external’ types. Internal ants stay in close proximity to the central brood cluster and tend to push stones away from it, while external ants repeatedly search for stones in the environment and push them directly towards the brood cluster until they collide with another ant or a wall.

The brood cluster and the internal ants that surround it serve as a *physical template* for construction, passively preventing stones from being pushed close to the brood cluster and actively moving stones away from it. Eventually, the built structure itself becomes more important for stigmergy and new stones are often bulldozed into or along existing walls. Building occurs in parallel in several places at once, with some stones travelling between building sites as different ants pick them up and drop them.

There is a certain ambiguity in the literature concerning the role of a *pheromone template* that emanates from the brood cluster. It is clear that ants use it to orient themselves within the nest (Franks et al., 1992), but it is not yet empirically established whether pheromone influences stone deposition directly (Franks and Deneubourg, 1997) leading existing models to differ in how they treat this aspect of ant behaviour (Franks et al., 1992; Theraulaz et al., 2003).

Furthermore, while global colony behaviour is well described (Franks et al., 1992) and modelled analytically (Franks and Deneubourg, 1997), existing agent-based simulations either use grid worlds where noisy movement and bulldozing with friction are not modelled (e.g. Franks et al., 1992) or implement simple continuous behaviour where ants are only of one type (e.g. Theraulaz et al., 2003). Moreover, Theraulaz et al. (2003) also model collisions abstractly, ide-

alising ant stone-dropping behaviour as influenced directly by the local density of stones as well as local pheromone concentration.

Here, we attempt to achieve a better understanding of how the radius and integrity of the constructed nest result from the physical interactions between ants, stones and pheromone in a continuous-space model, where some of the shortcomings of the previous models are addressed. In particular, the following hypotheses are tested:

1. Nests will be larger when there are more internal ants in the colony and smaller when there are more external ants.
2. Using pheromone as a building template will lead to more regular structures, but will also interfere with (1), above.
3. Nest entrances will form spontaneously, influenced by the density of the internal ants and facilitated by the pheromone template.

We also explore extensibility of the building behaviour:

4. It is possible for the same behavioural algorithm to generate alternative architectures by combining multiple pheromone clouds.

## Methods

All simulations were performed in a two-dimensional continuous-space arena of  $660 \times 660$  units ( $165\text{mm}^2$ , i.e. 1 unit =  $0.25\text{mm}$ ). Objects were scaled proportionate to their real-world counterparts using dimensions given by Franks and Deneubourg (1997). At the beginning of each run,  $3 \times 10^3$  rectangular stones of size  $2 \times 2$  units ( $0.5\text{mm}^2$ ) were placed randomly in the arena. The brood was represented by a tight cluster of 50 randomly oriented static ant agents placed around the middle of the arena in a random Gaussian fashion. A circular pheromone cloud 300 units in diameter was centred on the brood cluster such that the pheromone concentration had a constant value of unity at the centre, linearly decreasing to zero at the edge of the cloud. Time was modelled in discrete 0.02-second timesteps and each simulation run lasted 6000 seconds. All results presented in this paper are based on 20 runs per plotted data point.

Initially, a number,  $N_i$ , of ‘internal’ and,  $N_e$ , ‘external’ 10 units  $\times$  2 units ( $2.5\text{mm} \times 0.5\text{mm}$ ) ants were placed around the brood cluster. Ant location, orientation and movement were simulated as continuous (Bourg and Seemann, 2004, p.16–19), where the centre of an ant’s body was moved by a real-valued distance and given a real-valued orientation each time step. Collision detection prevented ants from moving over or through stones or other ants including brood members.

Modelled ants implemented the following empirically observed behaviours (Franks et al., 1992) by executing the algorithm represented in Figures 1–3:

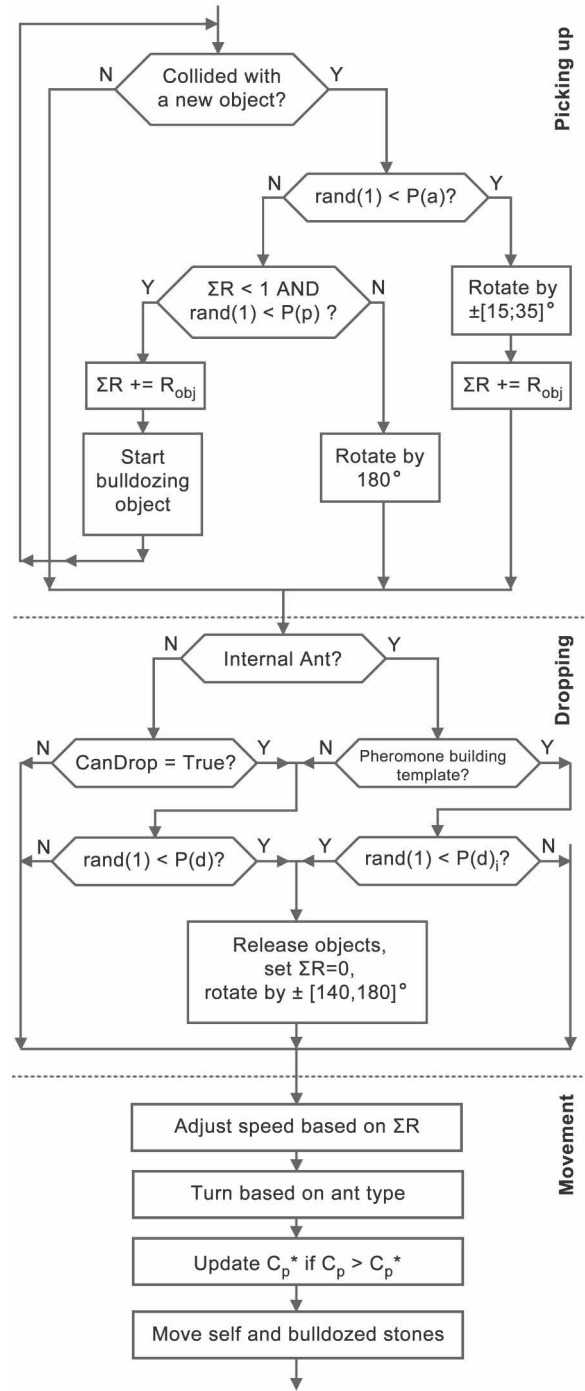

Figure 1: Ant behavioral cycle

1. Random movement, unless:

- bulldozing towards the brood cluster (external ants)
- bulldozing away from the brood cluster (internal ants)
- moving towards the brood cluster when pheromone levels were below a threshold (internal ants only)

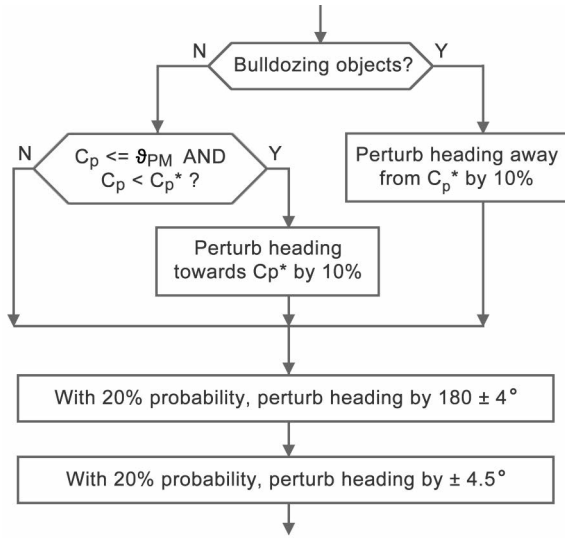

Figure 2: Internal ant's 'Turn based on ant type' routine

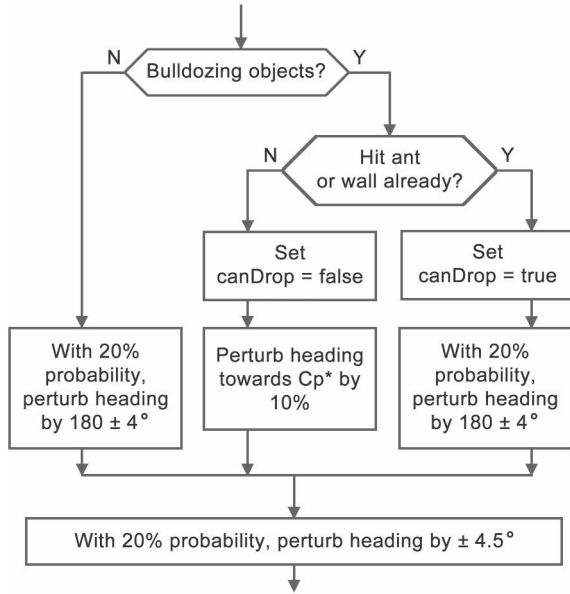

Figure 3: External ant's 'Turn based on ant type' routine

2. Stone bulldozing, i.e. pushing one or more stones forward
3. Stone dropping, the probability of which increased with felt resistance of whatever was being pushed or collided with
4. Occasional moving along walls while bulldozing. In this case, an ant rotated by a small value as it approached an existing wall and continued its movement along it.

In order to orient either towards or away from the brood cluster, both ant types relied on the ability to sense local

pheromone concentration,  $C_p$ , and on remembering the location of the highest pheromone concentration that they had encountered so far,  $C_{p*}$ : a proxy for the location of the brood cluster.

Internal ants (Figure 2) employed a pheromone movement threshold,  $\vartheta_{PM}$ , in order to remain within a characteristic distance of the central brood cluster. Where  $\vartheta_{PM} = 0$ , internal ants were free to roam to the edge of the pheromone cloud. Where  $\vartheta_{PM} = 1$ , internal ants attempted to remain as close to the brood cluster as possible. Internal ants tended to bulldoze encountered stones away from the brood cluster and then returned back. External ants (Figure 3) moved randomly unless they were bulldozing stones towards the brood cluster.

The probability of picking up stones when encountered was a constant  $P(p) = 0.5$ . Each bulldozed stone or stone that an ant was currently colliding with added resistance  $R_s = 0.15$  to the ant's total felt resistance  $\Sigma R \in [0, 1]$ . The resistance experienced during collisions with other ants was  $R_a = 1.0$ .

When an ant pushed more stones, its speed decreased (Equation 1), while its probability to move along walls  $P(a)$  and to drop stones  $P(d)$  increased (Equations 2 and 3), causing the colony to gradually extend existing walls rather than to make them thicker. Note that external bulldozers only started checking whether they should drop stones after they encountered an immovable obstacle and turned away from it, while internal bulldozers could drop stones at any time.

$$speed = 2 \times (1 - \Sigma R) \quad (1)$$

$$P(a) = \Sigma R \quad (2)$$

$$P(d) = f \times |\log(1 - \alpha \times (\Sigma R + \epsilon))|; \quad (3)$$

$$f = 0.625, \alpha = 0.8, \epsilon = 10^{-11}$$

In runs where the pheromone building template was employed, local pheromone concentration,  $C_p$ , influenced each internal ant's drop probability,  $P(d)_i$ , such that it exponentially increased as the ant moved towards edges of the pheromone cloud (Equation 4).

$$P(d)_i = \min(1, P(d) + |g \times \log(C_p)|); \quad (4)$$

$$g = 1/7$$

The combined effect of  $\Sigma R$  and  $C_p$  on  $P(d)$  and  $P(d)_i$  is depicted in Figure 4.

## Results

Structures built by the artificial ants were generally circular (Figure 5), with (sometimes incomplete) walls forming around the brood cluster at a characteristic distance that varied with model parameters. This result was robust with respect to the colony size and suitable values of the pheromone movement threshold,  $\vartheta_{PM}$ , and is comparable with the real and simulated ants in the existing literature (Franks et al., 1992; Theraulaz et al., 2003).

Figure 4: Contour plot of drop probability  $P(d)_i$  as a function of felt resistance,  $\Sigma R$ , and local pheromone concentration,  $C_p$ , based on Equations 3 and 4. In the absence of the pheromone building template, values of  $P(d)$  are dependant on Equation 3 alone and are plotted at  $y = 1$ , i.e. where the log of pheromone concentration is zero.

Figure 5: Example nests for various ant parameter combinations: (a)  $N_i=10$ ,  $\vartheta_{PM}=1.0$ ; (b)  $N_i=30$ ,  $\vartheta_{PM}=0.75$ ; (c)  $N_i=50$ ,  $\vartheta_{PM}=1.0$ ; (d)  $N_i=50$ ,  $\vartheta_{PM}=0.5$ . The pheromone cloud is shown as gray gradient. Brood clusters placed in the arena centres are shown in dark gray.

To check for the influence of stigmergy, we explored changes in the mean length of each bulldozing episode for external ants. As expected, the mean bulldozing duration, measured from when an external ant bulldozed into the pheromone cloud to the terminal collision, decreased over time irrespective of values of  $\vartheta_{PM}$  (Figure 6) due to the progressively higher frequency of encountering already placed stones. This behaviour is consistent with Franks and Deneubourg (1997), who implied that stone carrying time decays exponentially as the nest building progresses.

Figure 6: Fitted exponential models of mean bulldozing time measured for external ants between the moment they entered the pheromone cloud and the moment they dropped stones.  $N_i=30$ ,  $N_e=10$  and  $\vartheta_{PM}=1.0$  (solid,  $R^2 = 39.97\%$ ),  $\vartheta_{PM}=0.75$  (crosses,  $R^2 = 37.83\%$ ),  $\vartheta_{PM}=0.5$  (dots,  $R^2 = 28.04\%$ ). (Note that the inherent stochasticity of the simulation means that the exponential model does not account for all of the variance in bulldozing times.)

### Physical Building Template Only

We first explored building behavior in the absence of a pheromone building template.

The size of nests built by real ant colonies depended on the number of colony members (Franks and Deneubourg, 1997). Similarly, increasing the number of simulated internal ants,  $N_i$ , tended to increase the effective diameter of final structures (Figure 7a). Increasing colony size also increased the irregularity of the built structures, measured as the standard deviation of the number of stones found in eight regular conical sectors, each originating from the centre of the pheromone cloud (Figure 7b).

Both nest diameter and nest regularity were also dependent on the value of  $\vartheta_{PM}$ , i.e. on how far from the brood cluster internal ants were ‘willing’ to roam before turning back towards it. Only when  $\vartheta_{PM}$  was higher than a specific threshold value, was a colony able to effectively encircle itself with stones.

Where  $\vartheta_{PM}$  was high, internal ants were tightly clustered and regular circular nests were built relatively close to the central brood cluster. For runs with lower  $\vartheta_{PM}$ , internal ants spread out from the brood cluster, pushing the built structure out, but their lower density at the characteristic radius of the nest wall allowed gaps to form, compromising its regularity. For even lower values of  $\vartheta_{PM}$ , the internal ants were spread out to such an extent that they cease to be an effective physical template for building, allowing external ants to build much closer to the brood cluster. The critical value of  $\vartheta_{PM}$  (below which the physical building template fails) varied inversely with  $N_i$  as larger colonies could achieve sufficient density at greater distance from the brood cluster.

As  $\vartheta_{PM}$  approached zero and the density of internal ants was minimised, many stones were left very near the middle of the pheromone cloud, since external ants were often able to bring them to the brood and there was a lower probability

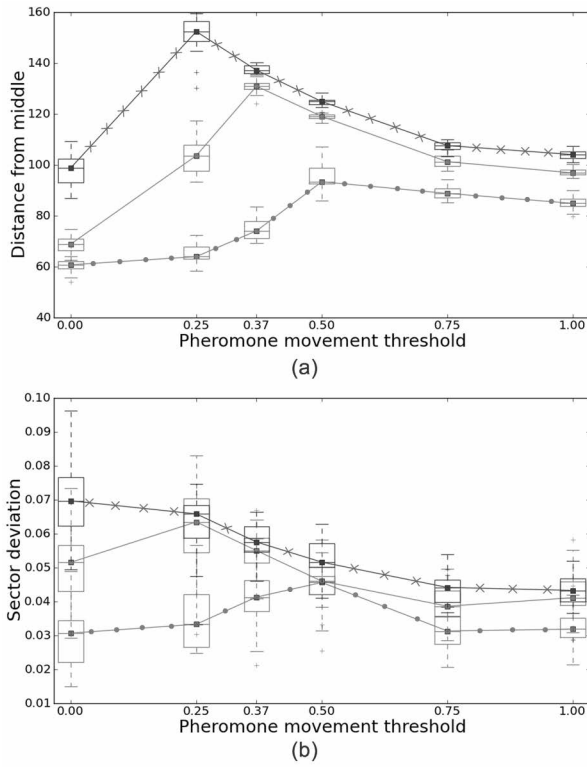

Figure 7: Influence of  $\vartheta_{PM}$  on (a) average distance of stones from the middle of the pheromone cloud, and (b) standard deviation of the number of stones in eight regular conical sectors of the cloud for  $N_e=10$  (all) and  $N_i=10$  (dots),  $N_i=30$  (solid),  $N_i=50$  (crosses).

of an internal ant encountering and removing them. In these cases, built structures were packed close to the brood and were often very irregular.

The number of external ants also had a non-trivial influence on building behaviour. With the number of internal ants fixed at  $N_i = 30$  we explored the influence of increasing external ant numbers from 10 to 180 for two pheromone thresholds,  $\vartheta_{PM} = 0.5$  and  $\vartheta_{PM}=1.0$ . Increasing the number of external ants,  $N_e$ , from 10 to 30 caused nests to become smaller, as expected, since increased pressure from external ants tended to establish walls closer to the brood cluster (Figure 8a). However, contra to Hypothesis 1, further increases to  $N_e$  gave rise to larger nests as a consequence of interference between external ants, some of which found themselves within the pheromone cloud during or after bulldozing, effectively augmenting the number of internal ants and amplifying the effect of their physical building template. Increasing the number of external ants,  $N_e$ , also tended to increase the amplification of their initial building sites, decreasing the regularity of built structures (Figure 8b).

In summary, this section has confirmed that model ants are able to achieve built structures the size and integrity of

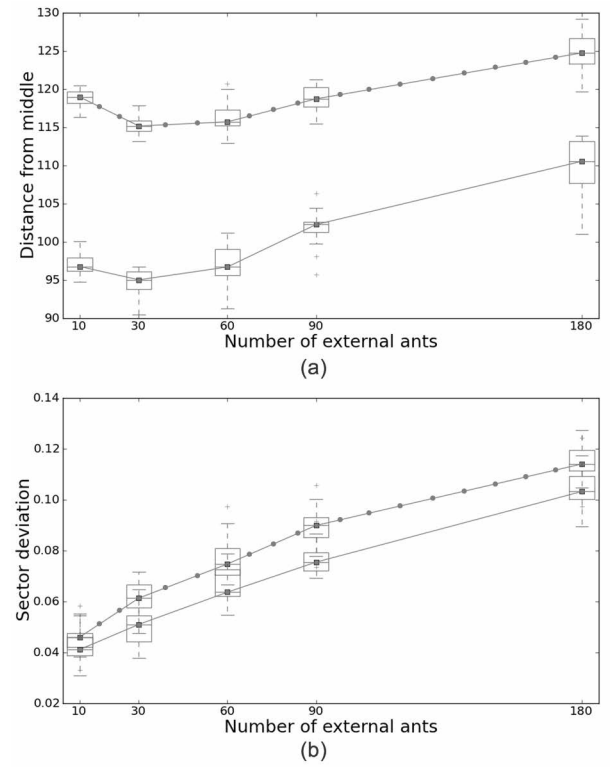

Figure 8: Influence of external ant number on (a) average distance of stones from the middle of the pheromone cloud, and (b) standard deviation of the number of stones in eight regular conical sectors of the cloud for  $N_i=30$  (all) and  $\vartheta_{PM}=0.5$  (dots),  $\vartheta_{PM}=1.0$  (solid).

which reflect a complicated interaction between the size of a colony and the extent to which internal ants tend to wander from the brood. They are able to achieve these structures in the absence of a pheromone building template, i.e. pheromone-mediated dropping behaviour is not necessary for successful nest formation. In the next section we explore the influence of such a pheromone building template and assess entrance formation.

### Physical+Pheromone Building Templates

The effect of employing a pheromone building template to encourage the dropping behaviour of internal ants (Equation 4) is depicted in Figure 9. Ants mostly tended to build smaller and more regular structures as dropping became more precisely tied to an internal ant's location within the pheromone cloud. This effect was more significant for larger colonies and those where internal ants roamed further from the brood cluster.

When the pheromone building template was used with large numbers of internal ants, e.g.  $N_i = 50$ , the influence of pheromone on building initially caused stones to be dropped closer to the brood cluster, but nests were subsequently ex-

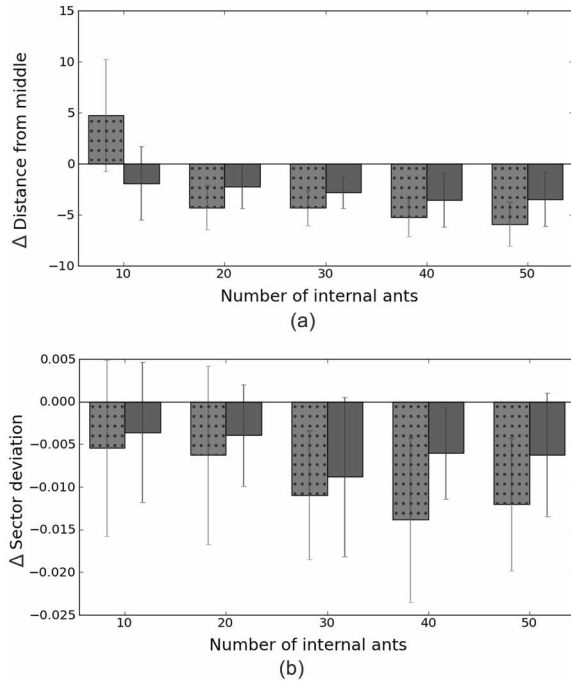

Figure 9: Difference between runs with and without pheromone building template in terms of (a) average distance of stones from the middle of the cloud where a negative number indicates smaller nests with pheromone building templates, and (b) standard deviation of the number of stones in eight conical sectors of the cloud where a negative number indicates more regular structures with the pheromone building templates, using  $N_e=10$  with  $\vartheta_{PM}=0.5$  (dots) and  $\vartheta_{PM}=1.0$  (solid).

panded to some extent due to the pressure of internal ants within the walls.

By contrast, when the number of internal ants was small, e.g.  $N_i = 10$ , and they remained close to the brood cluster ( $\vartheta_{PM} = 1.0$ ), the pheromone building template had little effect since internal ants rarely roamed a significant distance from the brood cluster.

However, when the same small number of internal ants were allowed to roam further from the brood cluster ( $\vartheta_{PM} = 0.5$ ), whereas without a pheromone building template they failed to achieve a nest wall, tending to assemble many stones in the middle of the cloud, with a pheromone building template more regular structures were achieved at an increased average distance from the brood cluster. In this case, the pheromone building template made nest creation possible when it otherwise would not be, by encouraging a wall to be built closer to the brood.

### Entrance Formation

Experimental runs were evaluated manually in order to categorise the final structures by number of entrances and

Figure 10: Proportion of nests with 0 (bars), 1 or 2 (light solid), 3 (dark solid) or more entrances (hatch) and irregular structures (dots) using (a)  $N_i=10$ , (b)  $N_i=30$  and (c)  $N_i=50$ . The individual groups are labeled using pattern  $N_e : \vartheta_{PM}$ . A star (\*) indicates that the pheromone building template was employed.

whether they could be considered nests at all (Figure 10). The most regular nests were built when 10 internal ants were used. Irregular nests (i.e. arrangements of stones that did not form a coherent structure at all) occurred only 5% of the time when  $\vartheta_{PM}=1.0$  and 15% of the time when  $\vartheta_{PM}=0.75$ . The frequency of nests with only 1 or 2 entrances increased as the number of external ants increased and similarly when the pheromone building template was used. However, in the latter case, the ants also built a complete wall with no entrances at all in 4/20 runs.

A similar pattern of entrance formation was observed in colonies with 30 internal ants, although generally the frequency of irregular structures increased in comparison with the previous case. Furthermore, these larger colonies tended to build nests with three or more entrances more often, especially when  $N_e = 30$  (12/20 runs). A nest with no entrances

was only built on one occasion when  $N_e=30$ .

The trend to create more entrances was even stronger for colonies with 50 internal ants. This was especially true when  $\vartheta_{PM}=1.0$ , in which case nests with four or more entrances formed in 11/20 runs. Interestingly, regularity of nests increased in comparison with colonies where  $N_i = 30$  ( $N_i = 30$  and  $\vartheta_{PM} = 0.75$  or  $\vartheta_{PM} = 1.0$ , regular nests occurred in 11/20 runs, while  $N_i = 50$ ,  $\vartheta_{PM} = 0.75$ , in 15/20 runs and  $N_i = 50$ ,  $\vartheta_{PM} = 1.0$ , in 12/20 runs). Nest regularity increased slightly in the experiments with pheromone building templates ( $N_e = 10$ ,  $\vartheta_{PM} = 1.0$  regular nests in 12/20 runs and in 14/20 runs during the pheromone building template experiments), although regular nests were the most frequent when  $N_e = 30$  and  $\vartheta_{PM} = 1.0$  (16/20 runs).

### Controlling Nest Shape

Standard structures created by ants with a single pheromone cloud were circular. In the following set of experiments, the pheromone cloud diameter was decreased from 300 units to 150 units and a number of clouds with brood clusters at their centres were arranged in order to create nests of different shapes.

Three experimental setups were created: a) rectangle: two clouds were horizontally aligned and the distance of their centres was set to 75 units, b) triangle: three clouds, the centers of which formed the vertices of a triangle with sides 75 units long, and c) square: four clouds, the centers of which formed corners of a square with 75 units side length. The number of external ants was 10, while there were always 10 internal ants per pheromone cloud. The value of  $\vartheta_{PM}$  was set to 1.0, since the previous experiments showed that the most regular nests were built with this value (Figures 7–10). Note that ants were unable to distinguish amongst the different sources of pheromone.

The final positions from 20 runs in each experiment were amalgamated in order to generate contour plots (Figure 11). In each experiment, the desired shape was always achieved, although there were no sharp corners as walls naturally curved around the boundaries of the individual pheromone clouds. Once again, using the pheromone building template facilitated creation of more regular structures, although it was not required to achieve the desired shapes.

One or two entrances usually formed along the shorter edges of rectangular structures. The triangular nests had one to three small entrances that could be found near the vertices. Entrances in square nests were usually more numerous and formed both along the edges and in the corners. Probably due to their size, square structures had the least regular distribution of stones in their walls.

### Discussion

Nest formation by simulated ants was tested in a number of different scenarios. The final circular structures, as well as the process by which they were built were comparable to real

Figure 11: Contour plots of nests created during the (a) rectangle, (b) triangle, and (c) square experiments. Results from experiments (1) without a pheromone building template, and (2) with such a template are shown. Pheromone clouds are represented by dotted circles. Crosses show arena centres, with brood clusters around them.

and previously simulated ants (Franks et al., 1992; Theraulaz et al., 2003) across a wide parameter space. Usually, the ants initially created a number of stone heaps that were gradually extended and connected together, while nest entrances remained clear throughout the process. Adding more external ants initially caused gaps in the nest wall to be created and destroyed, with stable entrances appearing only later in the simulations.

This building behaviour was more similar to that of real ants that clear a cavity of stones and create a number of progressively joined heaps rather than of those that bring stones from outside of the building site and gradually form a C-shaped nest with only one entrance (Franks et al., 1992). It is possible that in the latter case, external ants carry stones towards the nest from one direction, rather than from all directions as was the case in the simulated arena, or that they find stones further away from the nest, causing a slower stone intake rate and thus different wall formation dynamics.

The nest size varied as the number of internal ants increased, confirming the assumption of Hypothesis 1, although regularity of the structures decreased when they became large. The differences in nest size occurred due to variations in ant movement as large colonies required more space to spread out. Similarly, larger structures were formed when movement of ants within the pheromone cloud became less restricted by varying the  $\vartheta_{PM}$  parameter.

On the other hand, the assumption of Hypothesis 1 that

larger numbers of external ants  $N_e$  would cause higher pressure and lead to the creation of smaller nests was only true when  $N_e$  was relatively low. The nests actually became larger and less regular when  $N_e \geq 90$ . This surprising increase in nest diameter occurred because more external ants could be found inside the pheromone cloud, adding to the size of the physical template formed by the internal ants and brood. Nest regularity decreased as higher numbers of external ants assembled stones more rapidly, increasing the probability of amplifying any initial building sites.

Use of the pheromone cloud as a template for building improved nest regularity (Figures 9, 10, 11). Furthermore, the resulting structures were smaller as the gradient of pheromone concentration interfered with the effect of ant movement, confirming Hypothesis 2. This effect could not be observed with only 10 internal ants when they were restricted to remain very close to the centre of the pheromone cloud as they could not reach places influenced by the pheromone building template.

The fact that the pheromone template was not required for successful nest construction agrees with the assumption of Franks and Deneubourg (1997) who understood pheromone as simply a cue for ants to orient themselves within the nest. Allowing pheromone to influence stone deposition directly (e.g. Theraulaz et al., 2003) thus seems unnecessary.

The assumption of Hypothesis 3, that nest entrances would form when internal ant movement is more constrained ( $\vartheta_{PM}$  is high), was partially supported (Figure 10). When the number of internal ants was low,  $N_i = 10$ , more regular structures were produced for  $\vartheta_{PM} = 1.0$  compared to  $\vartheta_{PM} = 0.75$ . However, the effect of  $\vartheta_{PM}$  was not apparent when  $N_i = 30$  and was reversed when  $N_i = 50$ , i.e., the influence of  $\vartheta_{PM}$  on nest regularity varied with colony size. On the other hand, use of the pheromone building template always improved nest regularity, as predicted.

Finally, it was shown that non-circular nest shapes can be created when multiple pheromone clouds are arranged together (Figure 11), as predicted by Hypothesis 4. The clouds needed to be small enough so that there were enough stones available to create the final shapes and also suitably close to each other so that internal ants could travel between them.

## Conclusion

In conclusion, this work has helped to understand the building behaviour of the ant *Leptothorax tuberointerruptus* and to answer questions about the roles of colony size and pheromone-mediated behaviour in the building process. It is clear from the results presented here that even in the very idealised and simple scenario that we explore, the interactions that give rise to built structures are subtle and complex. We also show that this simple behavioural algorithm could perhaps be applied with cheap robotic ants to create structures beyond the circles achieved by *L. tuberointerruptus*. Extensions to the model include adding agent-generated

pheromone gradients, and applying the revealed principles of nest morphogenesis to the decentralised construction of more complicated heterogeneous architectures.

## Abstract

This paper discusses the co-evolution of social strategies and an efficiency trait in spatial evolutionary games. The continuous efficiency trait determines how well a player can convert gains from a prisoner's dilemma game into evolutionary fitness. It is assumed to come at a cost proportional to its magnitude and this cost is deducted from payoff. We demonstrate that cost ranges exist such that the regime in which cooperation can persist is strongly extended by the co-evolution of efficiencies and strategies. We find that cooperation typically associates with large efficiencies while defection tends to pair with lower efficiencies. The simulations highlight that social dilemma situations in structured populations can be resolved in a natural way: the nature of the dilemma itself leads to differential pressures for efficiency improvement in cooperator and defector populations. Cooperators benefit by larger improvements which allow them to survive even in the face of inferior performance in the social dilemma. Importantly, the mechanism is possible with and without the presence of noise in the evolutionary replication process.

## Introduction

Altruism – acting for the benefit of the group even if costly to the individual – is a widespread phenomenon in social and biological systems. Examples range from simple micro-organisms (Crespi, 2001) up to complex social interactions in society (Beinhocker, 2007). Various aspects of understanding the emergence and sustainability of such behaviour still poses a major challenge to evolutionary game theory (Weibull, 1996) and recent decades have seen very active research in the field (Wang et al., 2012; Szolnoki et al., 2009a; Szolnoki and Szabo, 2004; Tanimoto and Yamauchi, 2010; Masuda, 2007; Abramson and Kuperman, 2001; Tanimoto and Yamauchi, 2012; Santos et al., 2006a; Zimmermann and Eguíluz, 2005; Brede, 2011b; Perc and Wang, 2010; Wang and Perc, 2010; Szolnoki et al., 2009b; Szolnoki and Szabó, 2007; Brede, 2011a; Cao et al., 2011; Zhang et al., 2010; Szolnoki et al., 2010; Szolnoki and Perc, 2008; Szabo and Hauert, 2002; Perc and Szolnoki, 2008; Santos et al., 2006b; Brede, 2013b; Van Segbroeck et al., 2009; Szolnoki et al., 2012; Chadeaux and Helbing, 2010).

Models of the evolution of cooperation often build on the paradigmatic scenario described in the prisoner's dilemma.

In the simple one-off game two players are confronted with a simultaneous choice between two pure strategies, frequently labelled as “C” (for cooperate) and “D” (for defect). Depending on the combinations of choices, payoffs from the game are as follows. Mutual cooperation is rewarded with a payoff of  $R$  for both players, a player who plays “D” against “C” receives the temptation to defect  $T$  while the cooperator is paid the sucker's payoff  $S$  and mutual defection results in a payment of  $P$  for both players. For the prisoner's dilemma the ranking of payoffs is  $T > R > P > S$  and  $2R > T + S$ , such that the optimal choice for an individual who wants to maximize its own game outcome is always “D” while “C” is the optimal choice of a central planner interested in the good of the group.

A common explanation for the sustainability of cooperative strategies assumes positive assortment such that strategies of the same type can interact more often than when population structures are well mixed, cf. e.g., (Eshel and Cavalli-Sforza, 1983; Nowak and M., 1992). Such positive assortment can be facilitated by ‘network reciprocity’ in structured populations (Nowak, 2006; Szabó and Fath, 2007). Especially since the classification of prototypical network structures, like scale-free and small-world type networks, evolutionary game theory in structured populations has found growing interest. An important discovery in this line of research has been that cooperative strategies can receive a strong boost in populations that are coupled by very heterogeneous networks (Santos et al., 2006b), but notice the role of game participation costs in this effect (Masuda, 2007; Tanimoto and Yamauchi, 2010). Later work clarified that also other types of heterogeneity, e.g. in abilities of players to generate payoff (Perc and Szolnoki, 2008; Brede, 2011a) or in differing abilities of players to pass on strategies or adapt to neighbours (Szolnoki and Szabó, 2007; Wang and Perc, 2010; Perc and Wang, 2010; Tanimoto and Yamauchi, 2012), can give similar support for cooperation, even if the network of social interactions is regular.

Some recent studies have started to focus on the question how heterogeneity and game strategies can co-evolve, see (Perc and Szolnoki, 2010) for a review. The most prominent

approach in the field is probably to study adaptive networks in which social interactions change at a timescale similar to that of the evolution of game strategies (Zimmermann and Eguíluz, 2005; Santos et al., 2006a; Van Segbroek et al., 2008; Cao et al., 2011). A crucial assumption in these models is that agents have the cognitive abilities to break off undesirable ties.

Other models have considered the co-evolution of slow and fast strategy pass, e.g. via considering age-dependent abilities of agents (Wang et al., 2012), the co-evolution of performance evaluation rules (Brede, 2013b) or reinforcement of the position of abilities of agents who successfully passed on their strategies in past interactions (Szolnoki and Perc, 2008; Szolnoki et al., 2010; Zhang et al., 2010). As noted in (Brede, 2013a), common to these approaches is an assumption of a dynamics similar to Hebbian learning (Hebb, 1949): Successful interactions become stronger while unsuccessful interactions tend to decline in frequency. Whilst such processes based on Hebbian learning may be reasonable models of social interactions in many contexts, they still rest on ad-hoc assumptions (i.e. those of a Hebbian-like dynamics of system structure, or abilities to break unprofitable links (Van Segbroek et al., 2008) or some mechanism to influence group formation (Powers et al., 2011)) and do not provide a purely evolutionary framework that describes the co-evolution of system structure and social strategies via the same mechanism of evolution. Further, many of these models can only support cooperation if additionally constrained: I.e. in adaptive network models connectivities are typically held constant, or in the ageing-based models maximum ages are imposed, or in the reinforcement model the rate of reinforcement is found to be required to be within a certain range for optimal support of cooperation.

A recent paper addresses this gap and proposes a model in which traits of slow and fast strategy pass of agents can co-evolve with social strategies to support cooperation (Brede, 2013a). The paper proposes a framework in which agents can enhance their abilities to pass on strategies, albeit at a cost. Considering the binary options of ‘advertising’ (i.e. investing in fast strategy spread at a cost) or not advertising (i.e. normal strategy spread at no cost) the study demonstrates that cost-regimes exist, such that cooperation can associate with costly fast strategy spread while this is not viable for defection. It is easy to understand why this is the case: In comparison to defectors cooperators benefit from an investment to surround themselves with like types and thus they can afford to invest more in costly strategy pass than defectors. Hence, if strategy pass is costly enough, the usual competition between cooperators and defectors is replaced by a competition between fast spreading cooperators and slow spreading defectors, resulting in an evolutionary benefit to the former. The model of (Brede, 2013a) considers a binary choice (i.e. advertise or don’t advertise). Further,

the cooperation-supporting dynamics of (Brede, 2013a) relies on the crucial assumption of noise in strategy replication without which the mechanism of costly advertising cannot operate and the model is very sensitive to assumptions about joint inheritance of the advertising and the social strategies.

In this paper we consider a slightly altered modelling framework and illustrate that a co-evolutionary dynamics of agents with to a different extent enhanced abilities to generate payoff from the game can support cooperation even without these key ingredients of (Brede, 2013a), i.e. without the assumption of binary strategies, and without the assumption of noise in strategy replication.

## Model

Consider a spatially distributed population of  $N = L \times L$  agents that interact with their von Neumann neighbours. Agents are characterized by social strategies  $s \in \{C, D\}$  which they employ when playing a one-off prisoner’s dilemma game with their neighbours. The game is parametrized in the conventional way via  $R = 1$ ,  $T = 1 + r$ ,  $S = -r$  and  $P = 0$ . As usual the parameter  $r \in (0, 1)$  characterises the dilemma strength.

Every round an agent  $i$  earns payoff  $\pi$  from interactions with all four spatial neighbours. Further, every agent  $i$  is characterised by a trait  $\epsilon_i$  that determines the efficiency with which it can convert payoff gleaned from the game into evolutionary fitness  $f$  such that

$$f_i = (1 + b\epsilon_i)(\pi_i - c\epsilon_i). \quad (1)$$

The motivation for Eq. (1) is that every agent has a default mechanism to convert payoff into fitness at unit rate (represented by the term  $\pi_i$  in the expansion of (1)). However, after playing the game it can also invest an amount  $c\epsilon_i$  into higher efficiency conversion. Hence, after playing the PD game, a cost  $c\epsilon_i$  is deducted from game payoff and then the remaining payoff is converted into fitness. An alternative model is that the cost of efficiency improvements is deducted after payoff is converted into fitness, resulting in  $f_i = (1 + b\epsilon_i)\pi_i - c\epsilon_i$ . Both models result in qualitatively similar dynamics and we focus on the first choice in this paper.

In our model the trait  $\epsilon_i$  represents the ‘biological machinery’ to make use of payoff from the game,  $b$  measures its efficiency, and  $c$  is the cost (per unit of  $\epsilon$ ) to maintain it. In a biological context the cost of enhanced efficiencies could be seen as a cost to maintain a certain body mass, in a social context it might be associated with the maintenance of equipment or a cost to acquire certain skills. The assumption of a linear relationship between the size of the trait and the cost is for simplicity, in general it might be more reasonable to assume a different monotonic non-linear relationships, but this will not alter qualitative results.

We then carry out evolutionary simulations based on the following protocol:

- The lattice is seeded with random initial conditions, i.e. with probability 1/2 agents are assigned the social strategy  $C$  and with probability 1/2 social strategy  $D$ . Agents are also initialized with efficiency traits  $\epsilon$  selected uniformly at random from the interval  $[0, 1]$ .
- A focus agent  $i$  is picked at random from the population of  $N$  agents and one of its neighbours is selected at random as a reference agent  $j$ .
- Focus' and reference agent's payoffs  $\pi_i$  and  $\pi_j$  are evaluated and converted into evolutionary fitness according to Eq. (1).
- With probability

$$P(j \rightarrow i) = \frac{\exp(f_j/\kappa)}{\exp(f_j/\kappa) + \exp(f_i/\kappa)} \quad (2)$$

the focus agent  $i$  will adopt the reference agent  $j$ 's traits, i.e. the social strategy  $s_j$  and the efficiency trait  $\epsilon_j$  of  $j$ . As introduced in (Szabó and Toke, 1998) the parameter  $\kappa$  in (2) gives the noise level in the process of strategy spread. For  $\kappa = 0$  superior performers always replace worse performers, if  $\kappa > 0$  also less successful strategies have an occasional chance to invade a neighbours place. Note, that the noise parameter is of importance to contrast the present results with those of (Brede, 2013a), because the results of (Brede, 2013a) are not robust in the limit  $\kappa \rightarrow 0$  of (up to neighbour selection) deterministic updating.

- The process of game play and replication is iterated till a quasistationary state is reached and then average frequencies of cooperators and defectors and equilibrium averages over the evolutionary trait are calculated from a sufficient number of further iterations.
- The entire experiment is then repeated a sufficient number of times to evaluate from how many random initial conditions cooperation could evolve.

Numerical results presented below are generally obtained from simulations on  $200 \times 200$  tori and  $b = 2$  and have been repeated for at least 50 times to obtain estimates of the frequency of situations in which cooperation can arise.

## Results

This section describes and analyses numerical results obtained by simulations of the model introduced above. Figure 1 compares average trajectories of the co-evolution of the efficiency trait and social strategies for a case when the efficiency trait is costly and another in which it comes for free. Both scenarios are for the case of noiseless replication  $\kappa = 0$ . Notably, if efficiency is not costly, both cooperators (open boxes) and defectors (filled boxes) evolve to maximize efficiencies. Asymptotically, this results in a

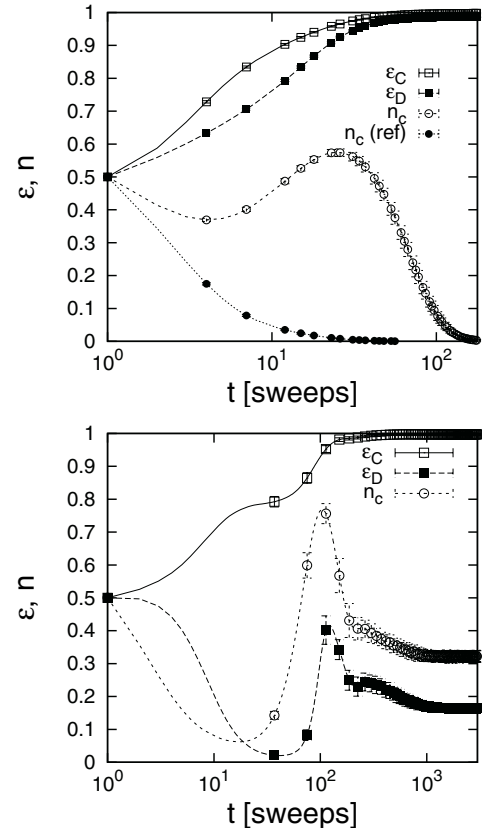

Figure 1: Co-evolution of social strategies and efficiency traits for (top)  $r = 0.01$  and cost  $c = 0$  and (bottom)  $r = 0.1$  and cost  $c = 1$  for  $\kappa = 0$ . Average trajectories for the density of cooperators  $n_c$  and the average efficiency trait of cooperators  $\epsilon_C$  and defectors  $\epsilon_D$  have been calculated from sampling the stochastic dynamics of the evolution over 1000 independent runs on a  $200 \times 200$  torus. For comparison the figure also contains the average evolution of cooperators in the standard one-off spatial game with  $\kappa = 0$  and  $r = 0.01$ . Note the logarithmic scale for the time domain.

homogeneous system in which payoffs are scaled by a factor  $1 + b$  and cooperative strategies cannot survive for even very low dilemma toughness ( $r = 0.01$  in this case). Interestingly, however, one also notes that in the initial stages of the dynamics average efficiencies of cooperators grow faster than those of defectors. The reason for this is simple: As extinction pressures are larger on cooperators than on defectors, also the evolutionary pressure on inefficient cooperators is larger than on inefficient defectors (which, if favourably positioned, can occasionally generate more fitness than efficient defectors at less favourable locations). The delayed saturation of efficiencies of defectors and cooperators leads to a dynamics that is different from the usual evolution in the one-off game (cf. the filled circles in Fig.

1). Cooperators can initially gain an advantage by associating with larger efficiencies than defectors and hence they can recover from the initial decline which is caused by the assortment dynamics after starting from random initial conditions. However, the recovery of cooperation is stopped as defectors evolve towards saturation in the efficiency trait and cooperators become extinct when a homogeneous state with  $\epsilon = 1$  is reached in the entire population.

The bottom panel of Fig. 1 contrasts the co-evolution of social strategies and efficiencies for  $c = 1$  and a much more severe dilemma setting with  $r = 0.1$  to the above scenario of a free efficiency trait with  $c = 0$ . For a better visual understanding also some snapshots in the evolution which correspond to important stages of the dynamics are illustrated in Fig. 2. One first notices the difference in the asymptotic states: For costly efficiencies cooperation can survive in a regime far beyond dilemma strengths which typically support cooperation in the spatial game with  $\kappa = 0$ . Concomitantly, cooperators associate with a saturated efficiency whereas defection is typically paired with much lower values of the efficiency trait. The course of the evolution is also different from the scenario with a free efficiency trait and proceeds in several stages. First, as typical in the evolution of cooperation in spatial games, when strategies are randomly mixed cooperators are easily exploited by defectors and hence cooperation declines until assortment of like strategies is reached. In the process only cooperators with large efficiencies survive in small islands (Fig. 2 top right, which corresponds to the minimum in the number of cooperators in Fig. 1) in a sea of defectors. Within the sea of defectors low efficiency investments are favoured (as there is hardly any game payoff to be leveraged) and large efficiency defectors only survive in very small numbers when attaching to clusters of cooperators. In a second stage, large efficiency cooperators can expand into the sea of low efficiency defectors, conquering a very large share of the entire system (Fig. 2, bottom right, corresponding to the maximum in cooperation in Fig. 1). With some delay this allows large efficiency defectors to expand and eventually a stationary balance of ordered arrangements of large and low efficiency defectors and large efficiency cooperators is reached (Fig. 2 bottom left).

These initial simulations illustrate an important point: A co-evolutionary dynamics of costly efficiencies and social strategies can allow cooperation to survive far beyond the regime normally supported by network reciprocity. The origin of the support mechanism is that evolution favours efficiency enhancements in clusters of cooperators. Since cooperators benefit from surrounding themselves with like strategies, paying a cost to surround themselves with other cooperators is an evolutionary viable strategy that outcompetes the cooperate strategy that does not invest into efficiency enhancements. For defectors the situation is different. When not in contact with cooperators, defectors which invest into

efficiency enhancements are outcompeted by defectors who don't. However, only efficient defectors manage to penetrate clusters of efficient cooperators and thus a cyclic dominance (efficient cooperators beat inefficient defectors, but are beaten by efficient defectors who are in turn outcompeted by inefficient defectors) similar to Rock-papers scissors (Szolnoki and Szabo, 2004), volunteering (Szabo and Hauert, 2002) or the advertising game of (Brede, 2013a) is created. As one would expect, the balance between the three competing strategies can be shifted when modifying the cost parameter. Interestingly, however, in a large cost regime high efficiency defectors can easily be pushed into extinction and for low frequencies of recurring invasions cooperators can dominate the system over large time periods.

For a more comprehensive investigation, in Fig. 3 the phase diagrams that give the dependence of the frequency of cooperators  $n_c$  on the dilemma toughness are evaluated for low, intermediate, and high noise levels in strategy replication. Going hand in hand with this Fig. 4 gives the dependence of stationary average efficiencies on the dilemma toughness parameter  $r$ . Both, the  $n_c(r)$  curves in Fig. 3 and the  $\epsilon_C(r)$  and  $\epsilon_D(r)$  curves in Fig. 4 are given for various cost assumptions.

For the case of noiseless replication with  $\kappa = 0$  several sharp transitions can be discerned. First, comparing curves for various cost choices it is worth noting that cooperation and efficiencies can co-evolve for any cost  $c > 0$ . This is illustrated by the first panel in Fig. 3: Whereas cooperation dies out for  $r > 0$  for  $c = 0$  cooperation can survive up to around  $r \approx 0.45$  if a small cost  $c = 0.0001$  is included (and in fact in the limit  $\kappa \rightarrow 0$  in Eq. (2) any cost makes sure efficient defectors can be invaded by  $\epsilon = 0$  defectors, thus allowing for the cyclical dominance mechanism to operate). As further illustrated in Fig. 5 this is different for  $\kappa > 0$ . The more noise in strategy propagation, the larger the cost required to allow cooperation to survive. On the one hand larger costs help the evolution of cooperation since they make it easier for inefficient defectors to chase efficient defectors, hence reducing the pressure on efficient cooperators and allowing them to thrive. However, on the other hand costs above some threshold make efficiency investments unviable for both cooperators and defectors. As a consequence a range of costs exists for which cooperation is optimally supported. The dependence of cooperation on dilemma costs also includes a transition which demarcates a phase in which efficient defectors typically survive the initial stages of the dynamics from another phase in which they go extinct (cf. Fig. 5). When efficient defectors die out, the cyclical competition is replaced by a competition between efficient cooperators and inefficient defectors in which the former can dominate. Hence, for some cost range a state in which only cooperators survive is reached. This state is marked by homogeneity in agent's efficiencies, and hence it is not stable to the reinvasion of defectors. In fact, including

Figure 2: Typical snapshots in the arrangement of cooperators (blue) and defectors (red) at various stages of the co-evolution. Clockwise from top right to bottom left: initial conditions at  $t = 0$ , then snapshots at  $t = 42$ ,  $t = 120$ , and the asymptotic state at  $t = 3000$ . The intensity of the color of the sites indicates the efficiency trait: dark blue corresponds to cooperators with large  $\epsilon$ , light blue to cooperators with low  $\epsilon$ , and dark red and light red refer to large  $\epsilon$  and low  $\epsilon$  defectors, respectively.

invasions of agents with randomly selected strategies, large amplitude oscillations between regimes in which cooperation dominates and regimes in which invading defectors can take over large parts of the system result.

Second, for  $\kappa = 0$  the  $n_c - r$  phase diagrams in Fig. 3 and the corresponding  $\epsilon - r$  diagrams in Fig. 4 show a number of sharp transitions in the  $r$ -dependencies. Whereas cooperators always evolve into a monochromatic population (not shown), the defector population tends to become separated into groups of defectors with high ( $\epsilon = \epsilon_C$ ) and low ( $\epsilon = 0$ ) efficiency. When the dilemma strength is increased, proportions of low and high efficiency defectors shift, but the values of the group-characteristic efficiency values  $\epsilon = 0$  and  $\epsilon = \epsilon_C$  remain the same. The first order transitions in the  $n_c - r$  dependencies indicate critical values of the dilemma strengths at which sudden shifts in the relative proportions of low and high efficiency defectors take place.

Most notable, in particular for larger costs, is the tran-

sition at which high efficiency defectors become extinct (i.e. at which  $\epsilon_D \approx 0$ ). The effect is similar to what we have discussed for the  $n_c - c$  dependencies in Fig. 5 above: Without the presence of high efficiency defectors low efficiency defectors are outcompeted by high efficiency cooperators and the latter can dominate the population. Whereas efficiency investments generally decline with increasing dilemma toughness, due to the efficiency competition in the now purely cooperative population, maximum efficiencies are favoured by evolution.

With the exception of smoother transitions between the various regimes, principally similar behaviour to the case of  $\kappa = 0$  is observed for intermediate and high levels of noise. The main difference is that more noise in strategy propagation requires larger costs of the efficiency trait for cooperation to persist.

Last, it is worthwhile examining whether the co-evolutionary mechanism is robust when strategy traits are

Figure 3: Dependence of the average stationary frequency of cooperators on the dilemma toughness  $r$  for noise levels in strategy updating  $\kappa = 0$  (no noise),  $\kappa = 0.1$  (low amount of noise), and  $\kappa = 1$  (large amount of noise). The dependencies are given for a range of cost parameters  $c$  for the efficiency trait. Note, that for  $c = 0$  and  $\kappa = 0$  and  $\kappa = 0.1$  cooperation can only survive for  $r = 0$  (open boxes).

inherited separately. To investigate this issue we consider an amended model in which the rules for passing on the social strategy  $s$  and the efficiency trait  $\epsilon$  are modified. If a focus agent copies from a reference agent (i.e. according to Eq.

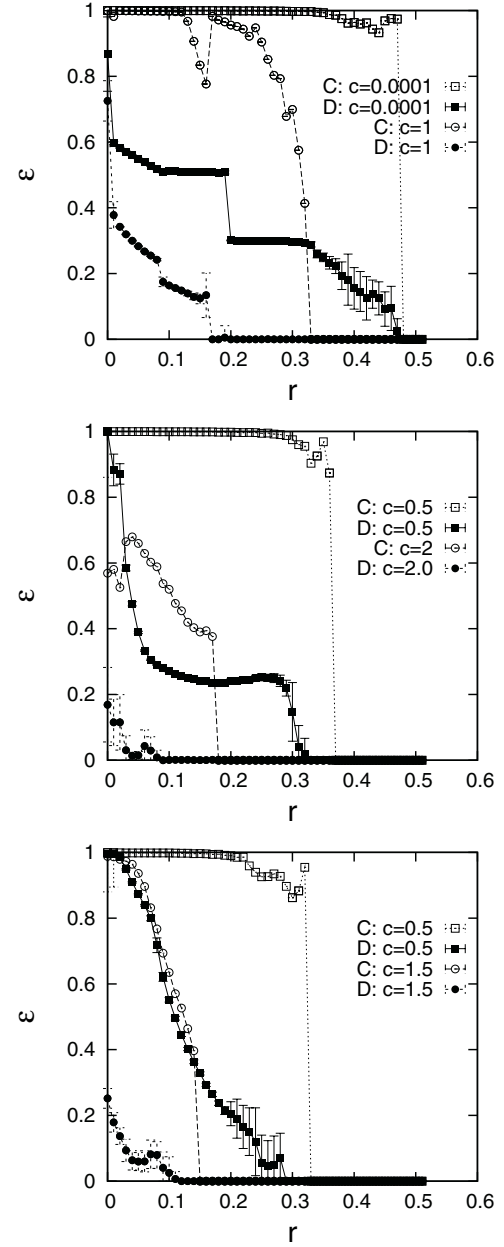

Figure 4: Dependence of the average stationary evolved efficiency traits of defectors (labelled as “D”, filled symbols) and cooperators (labelled as “C”, open symbols) on the dilemma toughness. (top) For  $\kappa = 0$  for two cost scenarios, very low cost  $c = 0.0001$  (boxes) and high cost  $c = 1$  (circles), (middle) for  $\kappa = 0.1$  and low  $c = 0.5$  (boxes) and high  $c = 2$  (circles) costs, (bottom) for  $\kappa = 1$  and low  $c = 0.5$  (boxes) and high  $c = 1.5$  (circles) costs.

(2)), with probability  $p_d$  only either the efficiency trait or the social strategy are imitated. In the opposite case, i.e. with probability  $1 - p_d$ , both traits are simultaneously passed on.

Figure 5: Dependence of cooperation on the cost of efficiencies for  $r = 0.1$  and several levels of noise in strategy propagation.

Figure 6: Dependence of cooperation on the dilemma toughness for various degrees of disjoint strategy pass  $p_d$  for  $c = 0.0001$  and  $\kappa = 0$ .

Hence the new parameter  $p_d$  classifies the degree of disjoint strategy pass, with  $p_d = 0$  corresponding to the previously considered model and  $p_d = 1$  corresponding to completely disjoint strategy pass. Figure 6 illustrates some simulation experiments in which scenarios with  $p_d > 0$  were explored. Clearly, disjoint strategy pass equalizes differences in efficiencies between cooperators and defectors, hence reducing support for cooperation. However, in contrast to the advertising game of Brede (2013a), cooperation can persist for rather substantial degrees of disjoint strategy transfer, thus adding robustness to previous results.

## Discussion and conclusions

In this paper we have considered a model for the co-evolution of social strategies and an efficiency trait that determines how well agents can convert gains from dilemma

games into evolutionary payoff. Through a series of controlled simulation experiments we have demonstrated that the co-evolution of efficiencies and social strategies can add substantial support to cooperation, if the payoff efficiency costs are within a certain range. Maximum and minimum costs that demarcate the cost window are dependent on noise in strategy replication, with lower noise generally allowing for a larger range of cooperation-supporting costs.

Even though based on a well-known cyclical dominance mechanism that has already been explored elsewhere (Szolnoki and Szabo, 2004; Szabo and Hauert, 2002), the present paper adds some significant extensions to the work of (Brede, 2013a). First, the change in the model from a trait that purely biases strategy spread to a trait that effects payoff generation adds an interesting aspect. The present paper demonstrates that pressures to enhance efficiencies are not the same for cooperators and defectors involved in evolutionary dilemmas on graphs. We demonstrate that the nature of the social game favours the evolution toward higher efficiencies in the cooperator population, and this, in turn, allows cooperation to survive.

Second, one might wonder whether the binary strategies imposed in (Brede, 2013a) constrain stationary states to settings that could not have been reached by the evolution of a continuous trait. We demonstrate here that this is not the case: A continuous efficiency trait can co-evolve with social strategies to support cooperation. The main difference compared to the binary setting is that stationary efficiency levels of the subpopulations self-organize to evolutionarily stable levels.

Third, the model presented in this paper demonstrates that the basic cooperation-supporting mechanism of (Brede, 2013a), i.e. that cooperators can afford to pay more for costly replication than defectors, is in fact more general than originally highlighted in the model based on learning and teaching. We show here that an equivalent mechanism based on costly efficiency improvements can also operate in evolutionary dynamics that are free of noise. For instance, some preliminary simulations indicate that qualitative results are robust for asynchronous updating based on ‘imitate the best’, for which no cooperation can survive in the standard spatial game (Huberman and Glance, 1993).

## Abstract

Explaining the long-term coexistence of many species in a complex ecosystem has been an important topic in both A-Life and ecology for several decades. Neutral and niche theories have been developed in parallel to explain ecological patterns of coexistence. Among the niche theories, trade-offs between species seem to play important roles in the mechanism of most models proposed so far. One of the many trade-off approaches to explain coexistence within trophic levels explores the scenario of species having two developmental stages existing in different ecological niches. Previous work has shown that such multi-stage models can sustain many species with inter-specific competitive coefficients larger than intra-specific ones for one of the stages, but the effect of such scenarios on the possible combinations for coexistence in the parameter space has not been explored. Here, we build on previous work by considering the effect of adding more stages to the competition model and analysing the relative sizes of the basins of attraction leading to coexistence. Computational simulations and Monte Carlo methods were used to analyse each number-of-life-stages case. The results show an increase in the number of coexistence cases between one and three stages. For more than three stages coexistence cases are reduced in relation to the parameter space due to the averaging effect of multiple competitive coefficients. The implications of such results could offer a potential explanation for coexistence patterns in ecology and adaptive ones in evolutionary biology.

## Introduction

The successful modeling of open-ended complexity in real ecosystems has long been a target for A-Life researchers (Channon and Damper, 2000; Channon, 2008; Shao and Ray, 2010; Ray, 1994). One of the great challenges for these models is achieving the long-term coexistence of a diverse collection of species. All too often the model collapses into a mono-culture or a small trophic cycle. One of the many simplifications that such models typically employ is to consider only a single life-stage for each of the species involved: there are only tadpoles, for example, and not both tadpoles and frogs. Here we show that including the possibility of multiple life stages can actually *promote* the persistent coexistence of multiple species, as Moll and Brown (2008)

have previously argued. Furthermore, we show that there is an optimal number of life stages to achieve long-term complexity, and that this number is a function of how quickly the environment fluctuates.

In current ecological literature a great number of theories and models have been developed in order to explore different biodiversity patterns (Chesson, 2000). Species coexistence models are concerned primarily with the basic problem of resource allocation among different species and the principle of competitive exclusion. These models attempt to generate *stable* coexistence over extended periods of time and they contrast with models of *unstable* coexistence which are concerned with mechanisms for delaying competitive exclusion by minimizing the differences between species fitness (Chesson, 2000; Moll and Brown, 2008). All *stable* coexistence models operate by establishing directly or indirectly a greater degree of intra-specific competition compared to inter-specific competition (Chesson, 2000).

Multiple Life-History Stage models are a type of stable coexistence model that depend on trade-offs. Here, the trade-off happens between different developmental stages of two or more species. In particular, these trade-off models show that the apparent coexistence of a great number of species is explained by the presence of many life-history stages with associated ecological niches. This is a phenomenon that has not yet been considered in the A-Life literature, and so in the current paper we draw on the relevant ecological literature to develop a simple dynamical-systems model of competing species with multiple life stages.

During their development, organisms of several species go through a series of phenotypic changes that affect the way they interact and exploit their environment (Werner and Gilliam, 1984). Drastic examples of these cases can be seen in insects (Dopman et al., 2007), amphibians (Werner and McPeck, 1994; Werner et al., 1995; Werner and Anholt, 1996) and fish (Arendt and Wilson, 1997). But similar interpretations can be extrapolated to plants with their different seed, sprout, juvenile, and adult stages, and plankton where different fluid dynamics and predatory pressures affect their interaction with the medium (Padisák et al., 2003). From

an evolutionary point of view, these differences between developmental stages allow juveniles to avoid direct competition with adults of the same species, and following Gillian's rule, evolution can move the population towards niche shifts where the ratio of mortality over individual growth is minimized (Werner and Gilliam, 1984; Claessen and Dieckmann, 2002). This process of adaptive niche shift during individual development is known as ontogenetic niche shift. From a competitive point of view, the picture that such systems show is one with an age-structured population where different species in the same guild and with similar developmental stages go through a stepped competition sequence where some individuals might do better than others at different stages (Moll and Brown, 2008; Fujiwara et al., 2011). The second diagram in figure 1 explains this approach for the simplest case of two species and two stages.

Previous work on this approach includes Moll and Brown (2008) and Fujiwara et al. (2011). But analysis on the coexistence space that such systems generate for every possible combination of competitive effects has not been explored. As a result, the hypothesis of coexistence in the parameter space being increased by ontogenetic niche shift has not been tested. Moll and Brown (2008) has proposed a very simple model to explain how coexistence could be possible in cases where inter-species competitive coefficients are greater than intra-specific ones (provided that this situation was restrained to only one life stage). An even more detailed model of the two-life-stages scenario is explored by Fujiwara et al. (2011), but in none of these cases has the extension to more life stages and the effect of ontogenetic niche shift on coexistence space been explored. In order to answer these questions, we propose a simplified version of Moll's model and we estimated the proportion of the hyper-dimensional parameter-space in which coexistence happens by using Monte Carlo techniques (Kroese et al., 2011) for a range of life-stage numbers.

### The Model

The most basic version of the model is described by two competing species with two life stages each, with competition between the life stages of a single species assumed to be absent. Equally, competition between the life stages of two different species is also assumed to be absent. Similar cases can sensibly be assumed to happen in nature in several species (Werner and Hall, 1988; Werner and McPeck, 1994; Werner and Anholt, 1996; Arendt and Wilson, 1997). The lack of competition between species and stages is an assumption for the sake of keeping the model tractable. Such competition could of course exist in the real world, but is not relevant to the question being asked here. Figure 1 shows the basic diagram for a single-stage, two-stage and three-stage competition models.

The discrete time-step version of the system shown in Figure 1 can be expressed with the following system of equations

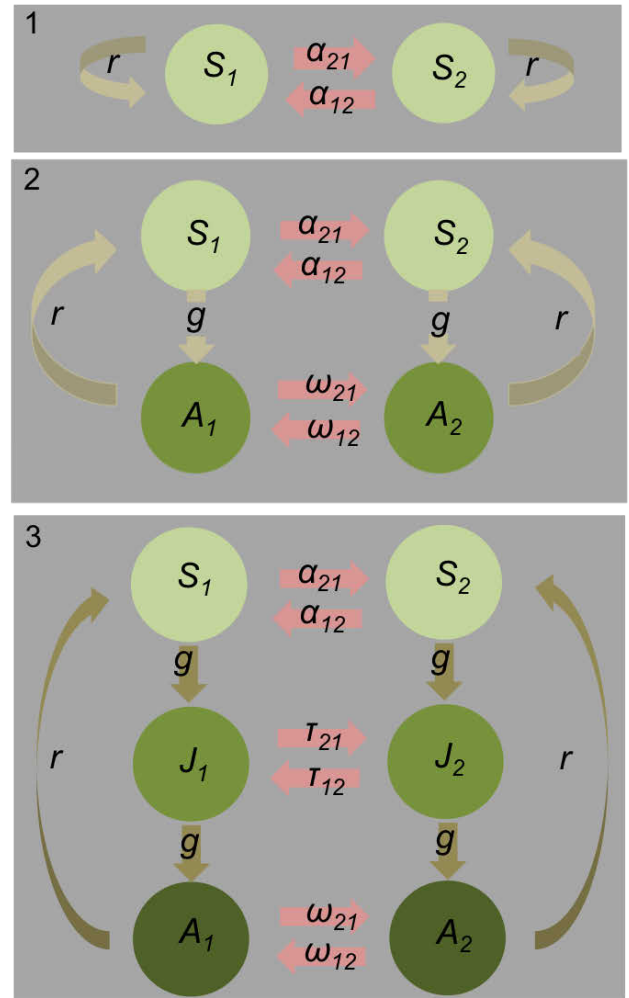

Figure 1: Diagrams for 1-stage, 2-stage and 3-stage models. Circles  $S$  and  $A$  represent the first and last stages respectively,  $J$  represents an intermediate stage between  $S$  and  $A$ ,  $r$  is the adult reproductive rate and  $g$  is the individual growth rate, and competition coefficients are represented by red arrows between circles, ( $\alpha$ ,  $\omega$  and  $\tau$ ). The model includes competitive effects in both directions and its values are standardized in relation to intra-specific competition. For instance,  $\alpha_{ij}$  corresponds to the effect of species  $j$  on species  $i$  in the first stage of development.

tions for an objective species  $i$ . These are modified and extended versions of Moll's model (Moll and Brown, 2008) which is itself based on a two species Ricker (1954) model.

$$S_{i,t+1} = r_i A_{i,t} e^{-(A_{i,t} + \omega_{ij} A_{j,t})} + (1-g) S_{i,t} e^{-(S_{i,t} + \alpha_{ij} S_{j,t})} \quad (1)$$

$$J_{i,t+1} = g(p_{i,t})e^{-(p_{i,t})+\chi_{ij}(p_{j,t}))} + (1-g)J_{i,t}e^{-(J_{i,t}+\tau_{ij}J_{j,t})} \quad (2)$$

$$A_{i,t+1} = g(p_{i,t})e^{-(p_{i,t})+\chi_{ij}(p_{j,t}))} + A_{i,t}e^{-(A_{i,t}+\omega_{ij}A_{j,t})} \quad (3)$$

Where  $S_{i,t}$  is the density of seeds of species  $i$  at time-step  $t$ ,  $A_{i,t}$  is the density of adults of species  $i$  and  $J_{i,t}$  is the corresponding to middle stages;  $r_i$  is the rate of growth from adults to seeds,  $g_i$  is the growth rate between stages.  $\alpha_{ij}$  is the competition effect of seeds of species  $j$  on species  $i$ ,  $\omega_{ij}$  is the equivalent for adults. The equation in the middle (Eq. 2) is the generic expression for any stage different from first or last; the value  $p_{i,t}$  corresponds to the density of individuals in the previous stage for time  $t$ . Concordantly, the parameter  $\chi_{ij}$  is a generic variable that corresponds to the competition coefficients in the previous stage. Intuitively it follows that  $\tau_{ij}$  refers to the competitive coefficient of stage  $J$ . Extensions to more stages follow by incorporating new density parameters and competition coefficients. The effects on every life stage are calculated accordingly considering the proportion of individuals that stay at that stage and the proportion that move to the next one. These systems of equations are deterministic but analytic solutions can not be found (Hassell and Comins, 1976). It is possible to look for isoclines in the tetra-dimensional space of the 2-stage model, but since the interest is in investigating percentages of parameter space that converge on coexistence for many different number of stages, a simulation approach was selected. In order to explore this system some simplifications were done in relation to the original Moll and Brown model. The effects of differences in growth rate and reproduction rate between species are not considered. For this reason, reproduction rates and growth rates are fixed as the same for both species, in this case defined by  $g$  and  $r$ . The individual growth rate between stages within a species is also considered as the same: in other words, individuals develop at a constant speed. The model also assumes the intra-specific competition to be 1.0 and the top density for any stage (determined by the load capacity of the system) is also assumed to be 1.0 (see Moll and Brown, 2008, for more information). Scaling terms are not considered following the assumption that competitive coefficients are relative to intra-specific ones.

## Methods

### Model Dynamics

In order to follow the effect of competition coefficients on the dynamics of the model the values of  $r$  and  $g$  were fixed,

on  $r = 1.5$  and  $g = 0.5$  (unless specified differently). The argument for the selection of these values was based on a preliminary exploration and will be discussed later. The simulations were run for 150,000 iterations or until the system reached equilibrium. This number of iterations was selected after running simulations across the parameter space and noticing no important differences between increases in iterations from this value on. The result of a particular simulation was assumed to be coexistence if no species became extinct (density under 0.00001 on at least one stage). In cases where one of the species turned out to be excluded the identity of the species was recorded. Initial densities or quantities were selected randomly for all simulations. To explore the most basic 2-stage version of the model, four conditions were selected for the  $\alpha_{ij}$  and  $\alpha_{ji}$  values. In the first condition both alphas were set to 1.0, making the intra-specific competition the same as the inter-specific one for the first stage. In the second case alpha values were selected below 1.0, making the first stage a coexistence scenario. The third case sets one alpha as greater than 1.0 and the other as less than 1.0, making the initial stage a competitive exclusion scenario. Finally, the last case considers both alpha values as larger than 1.0, which in a single-stage scenario will create alternate states dependent on initial density conditions for the four quantities. On each of these conditions a full 2D landscape for  $\omega_{ij}$  and  $\omega_{ji}$  was explored. The range explored was between omega values of 0.0 and 2.0 with a resolution of 0.01; at each of these points 50 simulations were run starting from random initial quantities for  $S_i$  and  $A_i$ , creating 200 X 200 x 50 simulation plots as shown in Figure 2 in the results section. These results can be considered a replication of those obtained by Moll and Brown (2008). As shown by Wilbur (1996) and Moll and Brown (2008) the model exhibits a range of behaviours from stable equilibrium to chaos to oscillations. In this work the range of parameters selected does not show any other behavior except simple attractors. In this case the space of exploration for the competitive coefficients goes between 0.0 and 2.0. Individual growth rates  $g$  between 0.01 and 0.99 were explored, as well as adult intrinsic reproduction rates  $r$  between 0.95 and 2.5.

### Exploring the 2-Stage Model

Each of the plots shown in Figure 2 could be interpreted as a slice of a tetra-dimensional space, where each dimension is characterized by the competition coefficients. On these slices the area of coexistence is a continuum square area that starts in the origin of the space (Moll and Brown, 2008, and Figure 2). With this knowledge, an estimation of the total hyper-volume of coexistence in the parameter space (from 0.0 to 2.0 on each dimension) could be obtained by estimating the omega values for which equilibrium coexistence stops being an attractor on both omega coefficients. In order to do this, one omega value is kept at 0.0 while the other explores simulations with values from 0.0 to 2.0 until coexis-

tence disappears. Once this has been done with both omega coefficients the proportion of the total coexistence area for that slice can be calculated by multiplying both omega values where coexistence does not happen any more, and then dividing this area over the  $2.0 \times 2.0$  area of search. Doing this with every combination of alpha values creates a 3D landscape where each combination of alphas have an associated percentage of coexistence space in the omega slice. The total space can then be estimated by averaging all the percentages and in this way we can calculate an estimate that can be checked with the Monte Carlo simulation results that will be explained in the next section. This 3D landscape is shown in Figure 3.

### Monte Carlo Simulations

In order to explore systems with more stages, a sensible way forward is taking random samples in the hyper-dimensional space and seeing in what proportions of these simulations coexistence is obtained. This approach is known as Monte Carlo search or ‘probing’. To do this, a large enough number of points should be selected to make a representative estimation. A set of tests were run using different numbers of points, and replicates. The conclusion was that 10,000 points and 10 replicates seemed to offer a good balance between small standard deviations and short simulation times. For each number of life stages between 1 and 10, Monte Carlo searches were performed (Figure 4). Also the effect of  $g$  and  $r$  values was tested and no qualitative differences were found.

### Results

Results are divided in two parts: first an exhaustive exploration of the basic 2-stage 2-species model is explored (Figure 2 and Figure 3). Secondly the results for the Monte Carlo simulations will show the coexistence percentage of the parameter space for systems with different numbers of stages (Figure 4).

#### Coexistence in the 2-Stage 2-Species Model

The simple 2-stage 2-species model was explored for 4 different scenarios regarding the competitive coefficients of the first stage; a similar approach was followed in Moll’s work. In the first case (Figure 2.A) the competitive coefficients for the first stage, or alpha values, were set to  $\alpha_{12} = 1.0$  and  $\alpha_{21} = 1.0$ . In this scenario the intra-specific and the inter-specific competitive coefficients for the first stage are exactly the same, which makes the system analogous to the 1-stage case, creating a 25% surface of coexistence for the omega slice. The second scenario (Figure 2.B) corresponds to the case where  $\alpha_{12} = 0.75$  and  $\alpha_{21} = 0.5$ ; these values were selected arbitrarily keeping in mind that they should be lower than one. Under this scenario the first stage suggests a coexistence case where inter-specific competition is lower than

Figure 2: Results for combinations of  $\omega$  values considering four different scenarios for  $\alpha$  values. Values were explored from 0.0 to 2.0 with a step resolution of 0.01, creating  $200 \times 200$  plots. Each point in this plot is the outcome of 50 simulations starting on random initial conditions for quantities  $S_i$  and  $A_i$ . For each simulation that species 1 won the point goes towards a red shift, for each simulation species 2 won the same happens towards blue. Coexistence is represented by purple, and in every instance is an attractor point (50 replicates converge to it). The figure shows how the coexistence region for the  $\omega$  space can be expanded depending on the values of  $\alpha$ . Plot A shows a case where competitive coefficients are equal to intra-specific ones, rendering the first stage ineffective in terms of outcome  $\alpha_{12} = 1.0$ ,  $\alpha_{21} = 1.0$ . The B plot shows a case where both alpha values suggest coexistence,  $\alpha_{12} = 0.75$ ,  $\alpha_{21} = 0.5$ . C shows the case where competitive exclusion would happen considering only the first stage  $\alpha_{12} = 0.5$ ,  $\alpha_{21} = 1.15$  and D shows the case where the initial stage would suggest an alternate state scenario  $\alpha_{12} = 1.25$ ,  $\alpha_{21} = 1.15$ .  $g = 0.5$ ,  $r = 1.5$ . Similar results can be found in Moll and Brown (2008).

the intra-specific. Such a case increases the area of coexistence when compared to the first scenario. Figure 2.C shows the omega space for the case  $\alpha_{12} = 0.5$  and  $\alpha_{21} = 1.15$ ; in this scenario the first stage suggests a competitive exclusion by species 1. In the space of possible second stage competitive coefficients this translates into a contraction of the coexistence space in the  $\omega_{21}$  axis and an expansion in the  $\omega_{12}$  axis, in relation to the first scenario. Finally, Figure 2.D shows the case where alpha values suggest alternate states dependent on initial conditions for the quantities  $S_i$  and  $A_i$  for every species  $i$ ; in this case the alpha values correspond

to  $\alpha_{12} = 1.25$  and  $\alpha = 1.15$  which creates a contraction in the coexistence area in relation to the first scenario.

Considering that the coexistence space remains as a continuous hyper-volume centred on the origin, a more exhaustive exploration of the space was performed. A plot that shows what percentage of the omega space (shown in the four scenarios of Figure 2) is composed by the coexistence region, per each combination of alpha values, was generated. Figure 3 shows such a plot, where the nonlinear nature of the coexistence space expansion for lower values of alpha justifies the increase in coexistence space in the 2-stage system compared to the 1-stage version. The implications of this, and its relation to further results in Figure 4, will be discussed below.

Figure 3: The figure shows the alpha space, where every combination of alpha has an estimated percentage of coexistence area in the omega space (Figure 2). The figure shows the non-linearity in the growth of the coexistence space for low alpha values. This in turn shows that the magnitude in cases where the coexistence area expands in relation to the 1-stage model (25% coexistence) is greater than the contraction in other cases.  $g = 0.5$   $r = 1.5$

### More Than Two Stages

Monte Carlo simulations for a range of multiple stage systems (from 1 stage to 10 stages) were run and the results are shown in figure 4; each bar represents the average value of 10 Monte Carlo runs with 10,000 random points in the entire parameter space; initial conditions for density quantities are randomly selected. Error bars, both positive and negative, represent a single standard deviation from the average. The decrease in coexistence space after 3 stages is due to the averaging effect of systems with many stages and it will be

discussed and explained in the next section. Dimensionality of the parameter space increases with stages but the number of points considered in the Monte Carlo simulations is enough for the standard deviations not to grow beyond sensible ranges.

Figure 4: Percentages of the hyper-dimensional parameter space for competition coefficients that converges to coexistence. Results obtained by 10 replicates of 10,000 point Monte Carlo searches. The error bars correspond to a single standard deviation. The proportion of the parameter space that converges to coexistence seems to be increased around a 3-stage scenario and then drop down when more stages are added.  $g = 0.5$ ,  $r = 1.5$ .

## Discussion

Ontogenetic niche shift is a well-documented process that produces a niche separation, and in some cases isolation, of different developmental stages in an organism's life. Previous theoretical work has shown that such processes can be interpreted as an adaptation that arises from the reduced intra-specific competition and associated fitness gain for individuals that exhibit some degree of separation between life-stage niches (Claessen and Dieckmann, 2002). In nature, cases of ontogenetic niche differences are abundant in plants, insects, amphibians, and fish. These cases offer a very clear picture of what it means to have two separate life stages with different niches. For instance, adult frogs and tadpoles live in different ecological niches, predated different sources of food, and being predated by different trophic levels. Similar cases can be seen in numerous species of fish that, during their development, move to different trophic levels and as a result to different ecological niches within the ecosystem (Werner and Hall, 1988). In the case of plants, which are of particular interest in coexistence research, different life stages can also be present. For instance, the environmental constraints and challenges during germination and plantule stages could be very different to the ones

present as fully grown adult plants (Eriksson, 2002). Although these scenarios strike us as obvious cases of ontogenetic niche shift, it seems hard to argue that coexistence of a large number of species in big communities (such as tropical forests or plankton communities) happens due to the effect of this characteristic on every single species evaluated. With respect to this point it is important to point out that such stages might not need to be obvious in the morphological sense for them to be functionally present. Certain ecological dynamics in terms of prey size (Mittelbach et al., 1988) and locomotion ability (Padisák et al., 2003) can happen with very small variations in phenotypic characters. In the same way, light capture and soil dependence could shift suddenly between different plant niches (Auffret et al., 2010). In other words, the presence of morphologically obvious differences between stages is an indication, but not a condition, for having different ecologically functional stages during development. Because the values for competition coefficients are relative to the intra-specific competition for that stage, and similarly individual growth and adult per capita reproductive rates are also relative to these values, similar results can be obtained with different competition coefficients and values for  $g$  and  $r$ .

### The 3 Stages Bump Explained

The most interesting result shown here is the increase in the size of the coexistence region that exists in the parameter space systems with 2, 3 and 4 stages. After this increase the coexistence region seems to shrink again when more stages are added (Figure 4). In this pattern there seems to be two different effects at work. First, the addition of more stages seems to increase the proportion of space that corresponds to coexistence; this is shown by the results in Figure 3, where the nonlinear increase of coexistence space for low  $\alpha$  values is bigger than the contraction for bigger ones, as in the case shown in Figure 2.D. Following this example it would be intuitive to assume that more stages allow for more coexistence; in a biological sense this translates to more scenarios where good outcomes in certain stages can maintain a species' survival despite bad outcomes in other stages. The drop in coexistence when adding more than three stages comes about because of a counteracting trend that happens when selecting random values for the competition coefficients. In order to understand the problem in an intuitive way, consider that every multi-stage system can be equivalent to a 2-stage case with different growth and reproduction rates. In Figure 5 a diagram explaining how to build an analogous 2-stage model from a multi-stage one shows how the randomly selected competition coefficients for the first stages tend to average around 1.0 for sampling between 0.0 and 2.0. This creates an analogous model where the first-stage competition is neutral to the outcome of the dynamics. In this way the incorporation of more stages approximates the model to the one described in Figure 2.A, where the

coexistence volume is close to 25%. This result is not an artifact in the sense that the Monte Carlo simulation is not biased in any way; the parameter space “eats” itself when more dimensions are added.

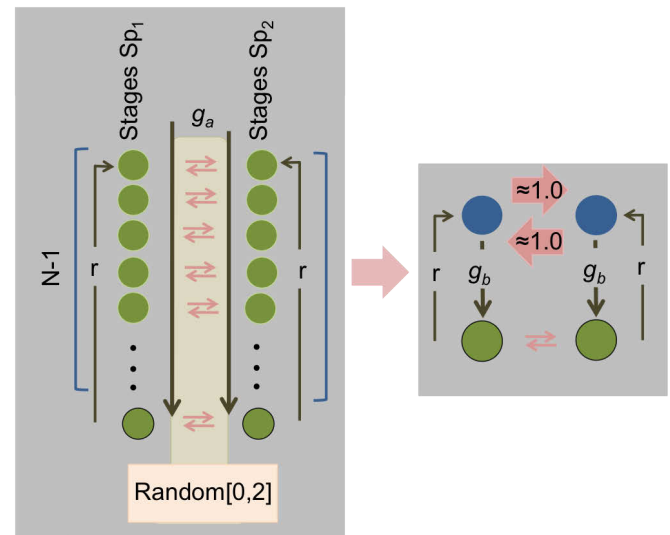

Figure 5: The detrimental effect of multi-stage systems on coexistence considering a system with  $N$  stages (left side); the random search for competitive coefficients in the space  $[0,2]$  will converge to a scenario where the inter-specific competition for the first  $N-1$  stages are analogous to a single stage with values close to 1. As shown in Figure 2.A this case represents a similar proportion to the single stage case, with only 25% of the space converging to coexistence. The only difference would be that in the analogous case the individual growth rate will be reduced due to the compression caused by merging  $N-1$  stages ( $g_a > g_b$ ), but this would not have an impact on single stage models.

Another way to understand this outcome is by considering the hypothetical case where the number of stages is infinite; in this case we would be looking at a continuous life development where competition only happens between same-age individuals. That scenario could also be analogous to noisy competitive abilities during development. In any of these two interpretations the effects of the two-stage niche segregation are lost, and the competitive coefficients can be averaged and considered as a single stage model, with 25% coexistence space in the range  $[0,2]$  for competitive coefficients. In nature, it can be sensibly assumed that over long periods of time the competition coefficient from the point of view of an objective species in relation to every competitor in a particular niche can vary. This would thereby create a pseudo-random sampling of competitive coefficients for every stage, over evolutionary timescales. It is tempting to state that under this consideration, the apparent presence of no-more-than-3 stages in most species with obvious ontoge-

netic niche shifts could be assumed as an adaptation for individuals of species that experience long term fluctuations of competitors in their different developmental niches. In order to test this hypothesis further work needs to be done, specifically taking into consideration the effects of reduction of intra-specific competition and co-evolutionary dynamics in multiple-species scenarios. Nevertheless, the results shown here suggest that such an idea could have the potential to explain such a trend in nature.

### Competition Between Stages

After a quick review of the results it might be apparent that this model relies heavily on the niche isolation between life-stages, which translates into diminished or absent vertical competition between stages. The effects of the inclusion of vertical competition will affect the results observed here depending on the magnitude considered. Hypothetically an equivalent scenario can be obtained if  $g$  and  $r$  rates are increased in certain stage transitions relative to others. The incorporation of vertical competition coefficients could show potential to explore a continuous spectrum with different degrees of isolation between stages. The expected result of such a model would be that at one end of the spectrum, where the impact of vertical (and diagonal) competition is fully considered, the model will converge back to the 1-stage scenario considering the competitive coefficient values as a function of all the coefficients involved. At the other end of the spectrum the effect uncovered by our model would be observed.

### More Than Two Species

In this work the considerations regarding competitive intransitivity between species were not analyzed. Nevertheless, the model proposed can be considered, in a simplified scenario, as a multiple-species case for any objective species  $i$ . Under this interpretation the effect of the second species can be said to be the weighted effects of all the species present in a particular niche. This is just an interpretation of the model, but in terms of the dynamics it does not capture the full effect of the competitive relations between species. Further work should be done in order to accommodate these cases.

### Natural Selection as a Promoter of Biodiversity

As a final point of discussion, it is important to consider in parallel the implications of: a) the results obtained in this work and b) the nature of ontogenetic niche shifting as an adaptation. As shown by Claessen and Dieckmann (2002) ontogenetic niche shifting can be seen as an individual adaptation responding to a pressure to reduced intra-specific competition. At the same time, ontogenetic niche shifting can potentially be seen as an adaptation to reduced inter-specific competition for objective species in changing environments. Such conclusions lead to a scenario where a process driven by natural selection at one scale promotes

coexistence and by extension biodiversity at another scale. Usually, natural selection has been seen as a process that reduces diversity in classic evolutionary theory. A further analysis of processes like the ones discussed here could show that under certain conditions natural selection can actually provide the basis for biodiversity rather than constrain it. Further analysis and model development to test this idea should be considered, but the result shown here seems to indicate that this could be the case.

### Conclusions

A review and classification of the current competition models that explain species coexistence framed the multiple life-history-stage version as a trade-off model. It was shown that such a model increases the percentage of the parameter space that converges to coexistence equilibrium points in cases with two, three and four stages. The effect is diminished by the incorporation of more than four stages due to the averaging effect of randomly occurring competitive coefficients, which effectively reduce the model to a single-stage case. The innovation of this piece of work relies on the approximation used to evaluate the coexistence space and the discovery of a non-linear pattern between the proportion of coexistence space and the number of stages. A set of more evolutionarily oriented simulations should be explored to determine the soundness of an adaptive explanation for biological species having no more than a particular number of life stages.

# Robustness and Directed Structures in Ecological Flow Networks

Taichi Haruna<sup>1</sup>

<sup>1</sup>Department of Earth & Planetary Sciences, Graduate School of Science, Kobe University,

## Abstract

Robustness of ecological flow networks under random failure of arcs is considered with respect to two different functionalities: coherence and circulation. In our previous work, we showed that each functionality is associated with a natural path notion: lateral path for the former and directed path for the latter. Robustness of a network is measured in terms of the size of the giant laterally connected arc component and that of the giant strongly connected arc component, respectively. We study how realistic structures of ecological flow networks affect the robustness with respect to each functionality. To quantify the impact of realistic network structures, two null models are considered for a given real ecological flow network: one is random networks with the same degree distribution and the other is those with the same average degree. Robustness of the null models is calculated by theoretically solving the size of giant components for the configuration model. We show that realistic network structures have positive effect on robustness for coherence, whereas they have negative effect on robustness for circulation.

## Introduction

Networks have been usually considered as undirected in the field of complex networks (Newman, 2003). However, many real-world networks are directed so that the direction of interaction is important for the functioning of the systems. Recently, it has been revealed that directed networks have richer structures such as directed assortativity (Foster et al., 2010) and flow hierarchy (Mones, 2013).

In our previous work, we proposed a new path notion involving directedness called lateral path that can be seen as the dual notion to the usual directed path (Haruna, 2011). Based on category theoretic formulation, we derived the lateral path as a natural path notion associated with the dynamic mode of biological networks: a network is a pattern constructed by gluing functions of entities constituting the network (Haruna, 2012). Thus, its functionality is coherence, whereas the functionality of the directed path is transport. We showed that there is a division of labor with respect to the two functionalities within a network for several types of biological networks: gene regulation, neuronal and ecological ones (Haruna, 2012). It was suggested that the two

complementary functionalities are realized in biological systems by making use of the two ways of tracing on a directed network, namely, lateral and directed.

In this paper, we address robustness of ecological flow networks with respect to the lateral path and directed path, respectively. Since the natural connectedness notion associated with the directed path is the strong connectedness, we consider robustness of the giant strongly connected component (GSCC) for the latter. For the former, robustness of the giant laterally connected component (GLCC) is of interest. Thus, we assess robustness of ecological flow networks in terms of two different functionalities, namely, coherence and circulation, both of which are important for the functioning of them (Ulanowicz, 1997).

Robustness of ecological networks is an intriguing issue in recent studies (Montoya et al., 2006; Bascompte, 2009). Initially, robustness of general complex networks has been argued qualitatively in terms of critical thresholds for the existence of the giant component (Albert et al., 2000; Cohen et al., 2001). For ecological networks, their robustness has been measured by the size of secondary extinctions (Solé and Montoya, 2001; Dunne et al., 2002). Here, we employ a recently proposed idea to measure robustness quantitatively (Schneider et al., 2011; Herrmann et al., 2011). As a first step, we consider only random failure of arcs. The size of giant components is measured by the number of arcs involved because laterally connected components are defined only on the set of arcs.

Here, we study the impact of realistic network structures on robustness with respect to the two functionalities. Two complementary measures of it are proposed by comparing the robustness of a given real network with that of the two null models: random networks with the same degree distribution and those with the same average degree. The robustness of the two null models is calculated by theoretically solving the percolation problem on the configuration model, random networks with an arbitrary degree distribution (Newman et al., 2001).

This paper is organized as follows. In Section 2, we develop a theory to calculate the size of GLCC and GSCC under

Figure 1: An example of lateral path.

random removal of arcs in the configuration model. In Section 3, we propose two measure for the impact of realistic structures on robustness of networks by using the theoretical result obtained in Section 2. In Section 4, the proposed measures are applied to 10 ecological flow networks. In Section 5, we discuss the results and indicate future directions.

### Random Removal of Arcs in the Configuration Model

In this section, we consider a percolation problem, random removal of arcs, in the configuration model with respect to the lateral connectedness and the strong connectedness.

A *lateral path* in a directed network is a path in the network such that the direction of arcs involved changes alternately (Haruna, 2012) (Fig. 1). Two arcs are called *laterally connected* if they are connected by a lateral path (Haruna, 2011). Lateral connectedness defines an equivalence relation on the set of arcs. Each equivalence class is called *laterally connected component*.

Since lateral connectedness is defined on the set of arcs, here we also consider strong connectedness for arcs. Two arcs are called *strongly connected* if there is a directed path from one arc to the other arc, and vice versa.

Let us consider a random directed network with degree distribution  $P(k_i, k_o)$ .  $P(k_i, k_o)$  is the fraction of nodes in the network with in-degree  $k_i$  and out-degree  $k_o$ . We make use of the generating function formalism (Callaway et al., 2000; Newman et al., 2001) to calculate the sizes of giant laterally or strongly connected components (in short, GLC-C or GSCC, respectively) after removing arcs uniformly at random with probability  $1 - \phi$ , where  $\phi$  is the occupation probability.

The generating function for  $P(k_i, k_o)$  is

$$G(x, y) = \sum_{k_i, k_o} P(k_i, k_o) x^{k_i} y^{k_o}. \quad (1)$$

The average degree  $z := \langle k_i \rangle = \langle k_o \rangle$  is given by

$$z = \frac{\partial G}{\partial x}(1, 1) = \frac{\partial G}{\partial y}(1, 1). \quad (2)$$

Let  $P_i(k_i) := \sum_{k_o} P(k_i, k_o)$  be the in-degree distribution and  $P_o(k_o) := \sum_{k_i} P(k_i, k_o)$  the out-degree distribution. Their generating functions are

$$F_0(x) := G(x, 1) \text{ and } H_0(y) := G(1, y), \quad (3)$$

respectively.

We introduce four excess degree distributions and corresponding generating functions that are necessary for the calculation in what follows.

First, let  $P_0(k)$  be the probability that the number of the other arcs arriving at the target node of a randomly chosen arc is  $k$  (Fig. 2 (a)). It is given by

$$P_0(k) := \frac{1}{z} \sum_{k_0} (k+1) P(k+1, k_0) \quad (4)$$

and its generating function is

$$F_{1,0}(x) := \sum_k P_0(k) x^k = \frac{1}{z} \frac{\partial G}{\partial x}(x, 1) = \frac{1}{z} \frac{\partial F_0}{\partial x}(x). \quad (5)$$

Second, let  $P_1(k)$  be the probability that the number of arcs arriving at the source node of a randomly chosen arc is  $k$  (Fig. 2 (b)). It is given by

$$P_1(k) := \frac{1}{z} \sum_{k_0} k_0 P(k, k_0) \quad (6)$$

and its generating function is

$$F_{1,1}(x) := \sum_k P_1(k) x^k = \frac{1}{z} \frac{\partial G}{\partial y}(x, 1). \quad (7)$$

Third, let  $Q_0(k)$  be the probability that the number of the other arcs leaving from the source node of a randomly chosen arc is  $k$  (Fig. 2 (c)). It is given by

$$Q_0(k) := \frac{1}{z} \sum_{k_i} (k+1) P(k_i, k+1) \quad (8)$$

and its generating function is

$$H_{1,0}(y) := \sum_k Q_0(k) y^k = \frac{1}{z} \frac{\partial G}{\partial y}(1, y) = \frac{1}{z} \frac{\partial H_0}{\partial y}(y). \quad (9)$$

Finally, let  $Q_1(k)$  be the probability that the number of arcs leaving from the target node of a randomly chosen arc is  $k$  (Fig. 2 (d)). It is given by

$$Q_1(k) := \frac{1}{z} \sum_{k_i} k_i P(k_i, k) \quad (10)$$

and its generating function is

$$H_{1,1}(y) := \sum_k Q_1(k) y^k = \frac{1}{z} \frac{\partial G}{\partial x}(1, y). \quad (11)$$

Figure 2: Four excess degree distributions. See the main text for details.

### Giant Laterally Connected Component

Let  $u$  be the average probability that an arc is not connected to the GLCC via a particular arc with the same target and  $v$  the average probability that an arc is not connected to the GLCC via a particular arc with the same source. Then, the average probability that an occupied arc does not belong to the GLCC is

$$\sum_{k,l} P_0(k) u^k Q_0(l) v^l = F_{1,0}(u) H_{1,0}(v). \quad (12)$$

Hence, the size of the GLCC is

$$L = \phi(1 - F_{1,0}(u) H_{1,0}(v)). \quad (13)$$

The values of  $u$  and  $v$  are calculated by the following set of equations:

$$\begin{cases} u = \sum_k Q_0(k)(1 - \phi + \phi v^k) = (1 - \phi) + \phi H_{1,0}(v) \\ v = \sum_k P_0(k)(1 - \phi + \phi u^k) = (1 - \phi) + \phi F_{1,0}(u). \end{cases} \quad (14)$$

The critical occupation probability  $\phi_{L,c}$  for the appearance of GLCC can be obtained from the linear stability analysis of the trivial solution  $(u, v) = (1, 1)$  of (14). It turns out to be

$$\phi_{L,c} = \frac{z}{\sqrt{(\langle k_i^2 \rangle - z)(\langle k_o^2 \rangle - z)}}. \quad (15)$$

### Giant Strongly Connected Component

The calculation of the size of the GSCC is similar to the node component case (Dorogovtsev et al., 2001; Schwartz et al., 2002). In (Serrano and De Los Rios, 2007), five notions of edge components are considered. For our purpose, consideration on the usual three components (in-, out- and strongly connected) as in the node component case are enough. However, these are implicit in the following calculation.

Let  $u$  be the average probability that an arc is not connected to the GSCC via a particular arc leaving from its target and  $v$  the average probability that an arc is not connected to

the GSCC via a particular arc arriving at its source. Then, the average probability that an occupied arc does belong to the GSCC is

$$\sum_{k,l} Q_1(k)(1 - u^k) P_1(l)(1 - v^l) = (1 - H_{1,1}(u))(1 - F_{1,1}(v)). \quad (16)$$

Hence, the size of the GSCC is

$$S = \phi(1 - H_{1,1}(u))(1 - F_{1,1}(v)). \quad (17)$$

The values of  $u$  and  $v$  are calculated by the following set of equations:

$$\begin{cases} u = \sum_k Q_1(k)(1 - \phi + \phi u^k) = (1 - \phi) + \phi H_{1,1}(u) \\ v = \sum_k P_1(k)(1 - \phi + \phi v^k) = (1 - \phi) + \phi F_{1,1}(v). \end{cases} \quad (18)$$

The critical occupation probability  $\phi_{S,c}$  for the appearance of GSCC is given by

$$\phi_{S,c} = \frac{z}{\langle k_i k_o \rangle}, \quad (19)$$

which is the same as in the node component case (Schwartz et al., 2002).

### Examples

We calculate the sizes of the GLCC and the GSCC as functions of the occupation probability  $\phi$  for three degree distributions: (a) Uncorrelated Poisson distribution (UPD)

$$P(k_i, k_o) = \frac{e^{-2\lambda} \lambda^{k_i + k_o}}{k_i! k_o!}, \quad (20)$$

(b) Uncorrelated exponential distribution (UED)

$$P(k_i, k_o) = \left(1 - e^{-1/\kappa}\right)^2 e^{-\frac{k_i + k_o}{\kappa}}, \quad (21)$$

and (c) Correlated Poisson distribution (CPD)

$$P(k_i, k_o) = \frac{e^{-\lambda} \lambda^{k_i}}{k_i!} \delta_{k_i, k_o}, \quad (22)$$

where  $\lambda, \kappa > 0$  are parameters and  $\delta_{k_i, k_o}$  is the Kronecker delta. The results are compared with numerical simulations in Fig. 3, which shows that the agreement between simulation and theory is well.

For critical occupation probabilities, we have  $\phi_{L,c} = \phi_{S,c} = 1/\lambda$  for UPD,  $\phi_{L,c} = (e^{1/\kappa} - 1)/2 < (e^{1/\kappa} - 1) = \phi_{S,c}$  for UED and  $\phi_{L,c} = 1/\lambda > 1/(\lambda + 1) = \phi_{S,c}$  for CPD. Thus, these examples also show that all possibilities  $\phi_{L,c} = \phi_{S,c}$ ,  $\phi_{L,c} > \phi_{S,c}$  and  $\phi_{L,c} < \phi_{S,c}$  actually occur.

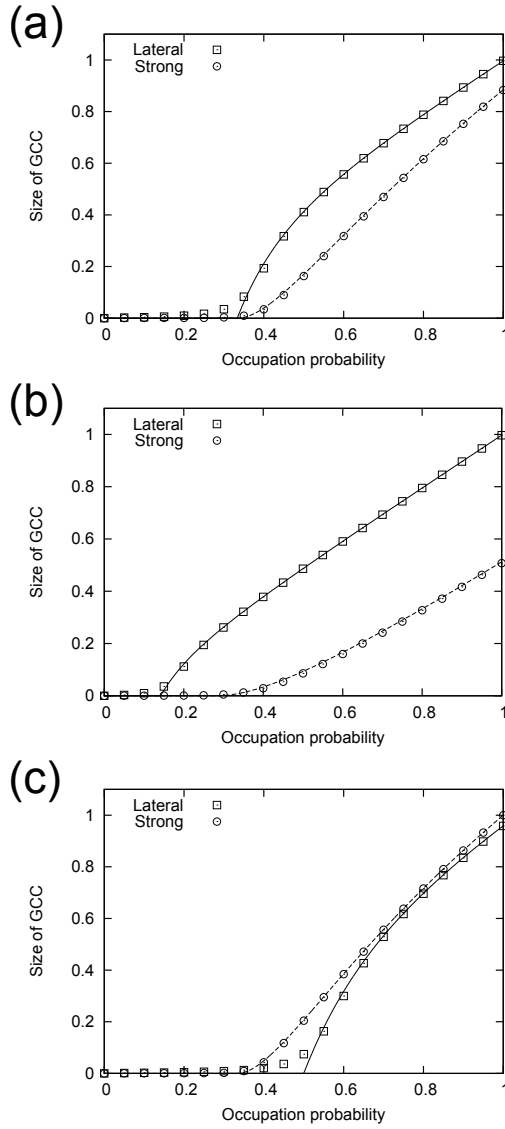

Figure 3:  $L(\phi)$  and  $S(\phi)$  for (a) the uncorrelated Poisson distribution with  $\lambda = 3$ , (b) the uncorrelated exponential distribution with  $\kappa = 4$  and (c) the correlated Poisson distribution with  $\lambda = 2$ . Lines are theoretically obtained. For (a) and (c), (14) and (18) are numerically solved. For (b), we obtain analytic expressions. Squares and circles are numerical simulations and averaged over 1000 different random removal sequences on different configuration model networks with the number of nodes 500 for (a) and (b), and 1000 for (c).

## Two Measures for Impact of Realistic Structures on Robustness

### Robustness

Given a directed network, let  $L(\phi)$  be the size of the GLCC and  $S(\phi)$  the size of the GSCC for occupation probability  $\phi$ .

Motivated by the robustness measure proposed in (Schneider et al., 2011; Herrmann et al., 2011), we define the robustness of the GLCC and that of the GSCC by

$$R_L = \int_0^1 L(\phi) d\phi \text{ and } R_S = \int_0^1 S(\phi) d\phi, \quad (23)$$

respectively.

Our robustness measure is similar to link robustness in (Zeng and Liu, 2012), however, since we measure the size of a component by the number of arcs belonging to it, it is different from link robustness. In particular, since  $L(\phi)$  and  $S(\phi)$  cannot exceed the diagonal line, we have  $R_L, R_S \leq 0.5$ .

### Gain

Given a directed network, we would like to consider how much its robustness (of the GLCC or the GSCC) is enhanced or degraded compared to a reference network. One measure is the ratio of the robustness of the given network to that of the reference network (Schneider et al., 2011). We call this measure *robustness gain*. If we denote the robustness of the given network by  $R_{given}$  and that of the reference network by  $R_{ref}$ , then the robustness gain is defined by

$$G_{given/ref} := R_{given}/R_{ref}. \quad (24)$$

We here consider three combinations of given-reference pairs: (given,ref)=(real, config), (given,ref)=(config, Poisson) and (given,ref)=(real,Poisson), where ‘real’ indicates a real-world network, ‘config’ the configuration model network with the same degree distribution and ‘Poisson’ the (uncorrelated) Poissonian network with the same average degree. The robustness gains for the three given-reference pairs are denoted by  $G_{r/c}$ ,  $G_{c/p}$  and  $G_{r/p}$ , respectively. Note that  $G_{r/p} = G_{r/c}G_{c/p}$ .

### Complement Ratio

The other way to measure the effect of realistic structures on robustness is to evaluate the amount of unrealized robustness of the reference network (namely,  $0.5 - R$ ) utilized by the given network. We define the *robustness complement ratio* for the above three combinations of given-reference pairs by

$$C_{given/ref} := \frac{R_{given} - R_{ref}}{0.5 - R_{ref}}, \quad (25)$$

where  $(given, ref) = (r, c)$ ,  $(c, p)$  or  $(r, p)$ .

Both  $G_{given/ref}$  and  $C_{given/ref}$  are considered for the lateral connectedness and the strong connectedness in next section. We write  $G_{L,given/ref}$  and  $C_{L,given/ref}$  for the former and  $G_{S,given/ref}$  and  $C_{S,given/ref}$  for the latter.

## Ecological Flow Networks

In this section, we apply the indexes introduced in previous section to relatively large 10 networks (with the number of

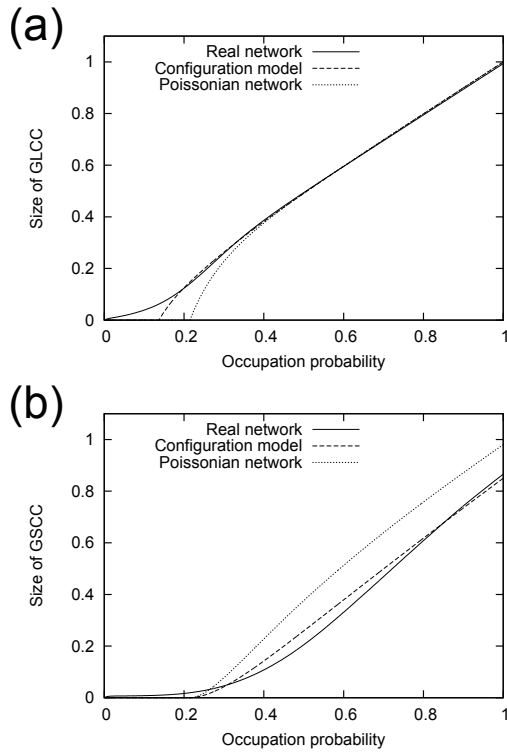

Figure 4: (a)  $L(\phi)$  and (b)  $S(\phi)$  for (vii) Middle Chesapeake Bay in Summer network (solid lines), those for the configuration model network with the same degree distribution (dashed lines) and those for the Poissonian network with the same average degree (dotted lines).

arcs  $> 100$ ) among 48 flow networks collected by R. Ulanowicz. Data are downloaded from <http://www.cbl.umces.edu/~ulan/ntwk/network.html>.

## Data

Here, we list the 10 ecological flow networks we analyze. In the following,  $N$  is the number of nodes and  $A$  is the number of arcs included in the largest weakly connected component.  $z = \langle k_i \rangle = \langle k_o \rangle$  is the average degree. The number associated to each network is the web number in the original data source. In every network, each arc indicates the existence of carbon flow from its source to target. (i) Chesapeake Bay Mesohaline Network ( $N = 26, A = 122, z = 3.4$ , Web 34). (ii) Everglades Graminoids Wet Season ( $N = 66, A = 793, z = 12.0$ , Web 40). (iii) Final Narragansett Bay Model ( $N = 32, A = 158, z = 4.9$ , Web 42). (iv) Florida Bay Wet Season ( $N = 125, A = 1938, z = 15.5$ , Web 38). (v) Lake Michigan Control Network ( $N = 34, A = 172, z = 5.1$ , Web 47). (vi) Lower Chesapeake Bay in Summer ( $N = 29, A = 115, z = 4.0$ , Web 46). (vii) Middle Chesapeake Bay in Summer ( $N = 32, A = 149, z = 4.7$ , Web

45). (viii) Mondego Estuary - Zostrea Site ( $N = 43, A = 348, z = 8.1$ , Web 41). (ix) St Marks River (Florida) Estuary ( $N = 51, A = 270, z = 5.3$ , Web 43). (x) Upper Chesapeake Bay in Summer ( $N = 33, A = 158, z = 4.8$ , Web 44).

## Results

We plot  $L(\phi)$  (Fig. 4 (a)) and  $S(\phi)$  (Fig. 4 (b)) for (vii) Middle Chesapeake Bay in Summer network, the configuration model network with the same degree distribution and the Poissonian network with the same average degree, as a typical example.  $L(\phi)$  and  $S(\phi)$  for real ecological flow networks are calculated by averaging the size of the largest connected components over 1000 random removal sequences of arcs.

The robustness values for all 10 networks are shown in Fig. 5. One can see opposite tendency on how realistic structures influence robustness between the GLCC and the GSCC.  $R_L$  tends to increase as more realistic structures are imposed on one hand,  $R_S$  tends to decrease on the other hand. However, since  $R_L$  is close to 0.5 already for the Poissonian-

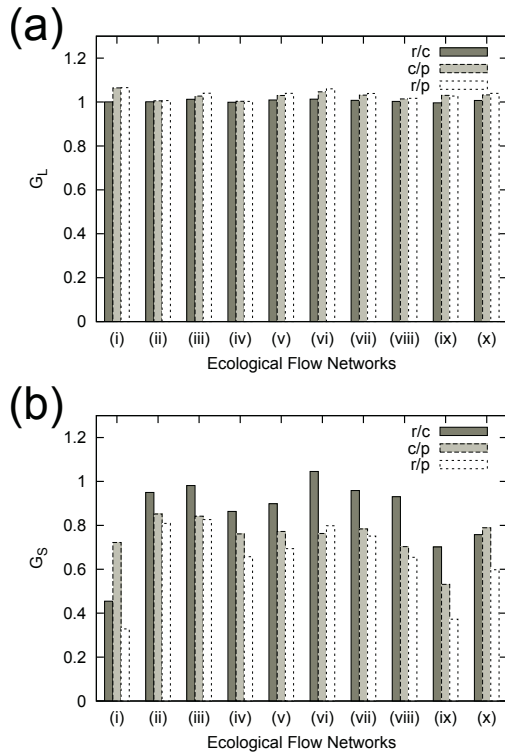

Figure 6: Robustness gain of the 10 ecological flow networks for (a) the GLCC and (b) the GSCC. Three given-reference network pairs are considered.  $r/c$ : (given,ref)=(real,config),  $c/p$ : (given,ref)=(config,Poisson) and  $r/p$ : (given,ref)=(real,Poisson). See the main text for details.

an network in most cases, the robustness gain for the GLCC is almost unity in all three given-reference pairs as seen in Fig. 6 (a). For  $R_S$ , one can see that the realistic degree distributions are the dominant factor for the degradation of robustness in most cases from Fig. 6 (b).

The tendency that realistic structures have positive impact on robustness of the GLCC can be captured more clearly by the robustness complement ratio as shown in Fig. 7. One can also see that the realistic degree distributions are the dominant factor to enhance the robustness of the GLCC in most cases.

## Discussions

Whether realistic structures of ecological networks have positive impact on their robustness or stability or not is controversial (Allesina and Tang, 2012). The answer to this question generally depends on the types of ecological interaction and dynamic processes of interest (Thébault and Fontaine, 2010; Allesina and Tang, 2012). In this paper, we focused on robustness of ecological flow networks under random failure of arcs with respect to the two different

Figure 7: Robustness complement ratio of the 10 ecological flow networks for the GLCC. Three given-reference network pairs are considered.  $r/c$ : (given,ref)=(real,config),  $c/p$ : (given,ref)=(config,Poisson) and  $r/p$ : (given,ref)=(real,Poisson). Data that have negative values are omitted.  $C_S$  has negative values except one case (data not shown). See the main text for details.

functionalities, namely, coherence and circulation. The former is captured by the robustness of the GLCC and the latter by that of the GSCC. We found that they exhibit opposite tendency for constraints by the realistic network structures: the realistic network structures enhance the robustness of the GLCC on one hand, they degrade that of the GSCC on the other hand. In both case, it is suggested that the realistic degree distributions are one of the most important factors.

The former result seems to be consistent with the food-web stabilizing factor proposed in (Gross et al., 2009): “(i) species at high trophic levels feed on multiple prey species and (ii) species at intermediate trophic levels are fed upon by multiple predator species”, because such patterns in a network could contribute to make multiple lateral paths between arcs. Whereas, the latter result could provide a quantitative support for the ‘autocatalytic view’ on ecological flow networks proposed by R. Ulanowicz (Ulanowicz, 1997).

Our result in this paper suggests that complex networks can be both robust and fragile in a different sense from that in (Albert et al., 2000): under the same attack strategy, robust for one functionality and fragile for another functionality.

It is of interest whether the same tendency can be seen or not for the other various attack strategies (Holme and Kim, 2002) and for the other kinds of directed biological networks such as gene regulation and brain. Research results on these issues will be reported elsewhere near future.

Countries and citizens often raise significant expectations every time a new International Environmental Summit is settled. Unfortunately, few solutions have come out of these meetings. This represents a challenge on our current understanding of models on decision-making: more effective levels of discussion, agreements and coordination must become accessible (Barrett, 2005).

Mitigating the effects of climate change requires cooperation, and arguably the welfare of our planet accounts for the most important and paradigmatic example of a public good game humans face: a global good from which every single person profits, whether she contributes or not to maintain it. However, these summits failed to recognize the well-studied difficulties of cooperation in public-good games. Indeed, in most cooperation problems faced by humans, individuals, regions or nations opt to be free riders, hoping to benefit from the efforts of others while choosing not to make any effort themselves driving the population into the tragedy of the commons. When dealing with such an essential public good as climate, many efforts are made to avoid this, so that efforts are shared for all and balanced measures can then be taken.

One of the multiple flaws often appointed to such agreements is a deficit in the overall perception of risk of widespread future losses, in particular the perception of those occupying key positions in the overall political network that underlies the decision process (Santos, Santos and Pacheco, 2008; Santos and Pacheco, 2011). Another problem relates to the lack of sanctioning mechanisms to be imposed on those who do not contribute (or stop contributing) to the welfare of the planet. Moreover, agreeing on the way punishment should be implemented is far from reaching a consensus, given the difficulty in converging on the pros and cons of some procedures against others, and (occasionally) narrow impact of punishment in promoting cooperative actions (Vukov et al., 2013). The impasse over these measures is expected since their consequences do not have a solid theoretical or even experimental background.

Here we discuss *i*) the effect of group size and risk awareness in the decision making process and *ii*) the emergence and impact of different types of sanctioning in deterring non-cooperative behavior in climate agreements, as reported in (Vasconcelos, Santos and Pacheco, 2013; Santos,

Vasconcelos et al. 2012). To this end, climate agreements are defined as Collective Risk Dilemmas (**CRD**), a simple Public Goods game with uncertainty that mimetizes the problem at stake (Santos and Pacheco, 2011). We model the decision making process as a dynamical process, in which behaviours evolve in time, taking into consideration decisions and achievements of others, which influence one's own decisions. We implement such behavioural dynamics in the framework of Evolutionary Game Theory, in which the individuals are simulated to respond to the most successful (or fit) behaviours. This way, one is able to describe strategic interactions between individuals, complemented by evolutionary principles. In particular, we do so in finite populations, where such fitness driven dynamics occurs in the presence of errors (leading to stochastic effects), both in terms of errors of imitation as well as in terms of behavioral mutations ( $\mu$ ), the latter accounting for spontaneous exploration of the possible strategies. Therefore, instead of resorting to complex and rational planning or rules, individuals revise their behavior by peer-influence, creating a complex dynamics akin to many evolutionary systems.

We consider, a population of finite size  $Z$ , in which individuals engage in the aforesaid  $N$ -person dilemma. Here, each individual is able to contribute or not to a common good, i.e. to cooperate or to defect, respectively. Game participants have each an initial endowment, or benefit,  $b$ . Cooperators contribute a fraction of their endowment, the cost,  $c < b$ , while defectors do not contribute. Irrespectively of the scale at which agreements are tried, they demand a minimum number of contributors to come into practice. Hence, whenever parties fail to achieve a previously defined minimum of contributions, they may fail to achieve the goals of such agreement (which can also be understood as the benefit  $b$ ), being this outcome, in the worst possible case, associated with an appalling doomsday scenario. To encompass this feature in the model we require a minimum collective investment to ensure success: if the group of size  $N$  does not contain at least  $M$  contributors, all members will lose their remaining endowments with a probability  $(1-r)$ , the risk; otherwise, everyone will keep whatever they have. Hence,  $M < N$  represents a coordination threshold necessary to achieve a collective benefit. We obtain an unambiguous agreement with recent experiments, together with several concrete predictions:

we address the impact of risk in several configurations, from large to small groups, from deterministic towards stochastic behavioral dynamics. Overall, we show how the emerging dynamics depends heavily on the perception of risk.

We find that the impact of risk is enhanced in the presence of small behavioral mutations and errors and whenever global coordination is attempted in a majority of small groups under stringent requirements to meet co-active goals (Santos, Vasconcelos et al. 2012). This result calls for a reassessment of policies towards the promotion of public endeavors: instead of world summits, decentralized agreements between smaller groups, possibly focused on region-specific issues, where risk is high and goal achievement involves large quorums for agreement, are prone to significantly raise the probability of success in coordinating to tame the planet's climate.

We also show how individuals may effectively self-organize their actions towards cooperation, by creating community enforcement institutions that are able to punish those who row against collective interest. We present the effects of punishment via institutions when playing against defectors (which leads to higher-order cooperation dilemmas). Moreover, we offer insights on the scale at which such institutions should be implemented, providing better conditions both for cooperation to thrive and for ensuring the maintenance of such institutions (Vasconcelos, Santos and Pacheco, 2013). This result is particularly relevant whenever perception of risk of collective disaster, alone, is not enough to provide the means to achieve a cohesive configuration – in this case, sanctioning institutions may provide an escape hatch to the otherwise tragedy of the commons that humanity is falling into.

This model provides a “bottom-up” approach to the problem, in which collective cooperation is easier to achieve in a distributed way, eventually involving regions, cities, NGOs and, ultimately, all citizens. Moreover, by promoting regional or sectorial agreements, we are opening the door to the diversity of economic and political structure of all parties, which, as showed before can be beneficial to cooperation. Naturally, we are aware of the many limitations of a bare model such as this, in which the complexity of human interactions has been overlooked. From higher levels of information, to non-binary investments, additional layers of realism can be introduced in the model. Moreover, even from a modeling perspective, several extensions and complex aspects common to human socio-economical systems could be further explored. On the other hand, the simplicity of the dilemma introduced here, makes it generally applicable to other problems of collective cooperative action, which will emerge when the risks for the community are high and high-level institutions may self-organize, something that repeatedly happened throughout human history, from ancient group hunting to voluntary adoption of public health measures. In light of our results in which bottom-up approaches are clearly favored by evolution and self-organization, the widely-repeated motto “Think globally but act locally” would hardly appear more appropriate.

## Abstract

We demonstrate that neural agents can evolve behavioral sequences of arbitrary length. In our framework, agents in a two-dimensional arena have to find the secure one among two possible patches, and which of them is secure changes over time. Evolution of arbitrarily long behavioral sequences is achieved by extending the neuroevolution method NEAT with two techniques: Only newly evolved network structure is subject to mutations, and inputs to the neural network are provided in an incremental fashion during evolution. It is suggested that these techniques are transferable to other neuroevolution methods and domains, and constitute a step towards achieving open-ended evolution. Furthermore, it is argued that the proposed techniques are strongly simplified models of processes that to some degree occur naturally in systems with more flexible genetic architectures.

## Introduction

Evolutionary robotics is an approach towards the design of controllers (and possibly also bodies) of robots that uses a process of artificial evolution. The controllers of the resulting robots are often in the form of artificial neural networks. It is conceivable that eventually robots with very complex goal-directed behaviors can be designed using this method. However, past work in the field has typically produced behaviors that are very simple as compared to behaviors of conventionally designed robot controllers.

Complex behaviors can arise by the interplay of environment, body, and controller even if the controller itself is not very complex (Pfeifer and Gómez, 2005). Nevertheless, within a given environment, there is obviously a correlation between the complexity of the controller and the complexity of the behavior. Therefore, it is desirable to have methods for the evolution of neural networks that can make the networks more and more complex over time.

For many of the earliest evolutionary robotics experiments, neural networks with a fixed topology, i.e., a fixed number of nodes and connections, were used (Nolfi and Floreano, 2000). That way, the achievable complexity is obviously limited. Later, a method called NEAT was introduced (Stanley and Miikkulainen, 2002). This neuroevolution method starts evolution using networks without any

hidden nodes and subsequently adds neurons and connections by carefully designed mutation operators. It has been shown that complexification during evolution does indeed occur when using NEAT, and can lead to neural networks with in the order of, say, 10 to 20 hidden nodes (Stanley and Miikkulainen, 2004). NEAT has subsequently been widely used for various evolutionary robotics experiments.

Of course, ultimately one needs more complexity than that evolved by NEAT and similar methods. Therefore, a more recent trend in neuroevolution is the development of methods that use developmental or generative encodings for neural networks, which enables them to produce large neural networks from comparatively small genomes. Examples of such methods include HyperNEAT, NEATfields and Compressed Network Complexity Search (Stanley et al., 2009; Inden et al., 2012; Gomez et al., 2012). These methods enhance the scalability of neuroevolution significantly as compared to methods using a simpler direct encoding like NEAT.

While evolution can produce comparatively complex networks with hundreds of neurons using these methods, the complexity of the behavior that can be produced by evolution (i.e., adaptive behavior, not just random behavior) is still subject to some limitations. These limitations arise from the fact that a genome consisting of  $l$  elements, each of which can be chosen among an alphabet of size  $b$ , can encode a choice between  $b^l$  different phenotypes at most. Depending on the method used, this can mean that the maximum size of the encoded network will be limited (unless it is preset by the experimenter like in standard HyperNEAT) or the maximum algorithmic complexity of its connection pattern will be limited (unless the encoding includes techniques that refer to externally or environmentally supplied sources of complexity). Even if none of those two limitations apply, the fact remains that the number of referentiable phenotypes is limited, so the complexity behavior as achieved by selection remains limited unless the genome length  $l$  is increased. However, a selection-driven unlimited increase of  $l$  is usually not possible even though the methods allow for it in principle. To see why this is so, consider what happens as more and more genes are added to a given genome. If the mutation

rate per gene is fixed, then more and more mutations will arise in one genome as it gets longer. At some point, mutation will destroy the information in the genome despite the presence of selection. In the theoretical biology literature, this point is known as error threshold (Eigen, 1971; Stadler and Stadler, 2003). However, many neuroevolution methods (among them NEAT) typically apply only one mutation per genome regardless of its size. That way, mutations will not overpower selection, but on the other hand, per gene mutation rates will decrease. Together with them, the mutation rates on individual features of the phenotype will also decrease. As we are interested in adaptive behavior of increasing complexity, which consists of more and more individual features, the waiting times for adaptive changes of or extensions to particular features will increase until evolution practically comes to a halt. One common way of describing this is saying that the search space increases exponentially with the number of variables (the variables correspond to the phenotypic features here). One might think that as this happens, new opportunities arise for evolution in the form of extradimensional bypasses (Conrad, 1990; Bongard and Paul, 2001), but it is unlikely that this effect keeps pace with the increase of the search space for fitness functions as typically used in evolutionary robotics. In fact, it is a common heuristic in neuroevolution to make the search space as small as possible by use of prior information on the task. The NEAT method also starts with the smallest possible neural network topology and only then gradually explores larger topologies just to keep the search space small.

However, there is a way for evolution to avoid this dilemma: by changing the genetic architecture such that mutations will with a higher than random probability hit the right places. Ideally, successful features of an organism would be conserved by reducing the local mutation rates, whereas features under adaptive evolution would have increased local mutation rates. Mutation rates can be changed either by changing local application rates of particular mutation operators (like in some variants of self-adaptive evolution strategies (Beyer and Schwefel, 2002)), or by changing the mutational target sizes of the respective features if the used encoding and mutation operators allow for such reorganizations of the genetic representations of those features. In fact, it has been shown in simulations using the artificial life system AVIDA that the representations of conserved features can become compressed over time just by applying normal mutation and selection (Ofria et al., 2003). In principle, these changes of genetic architecture might also arise when using methods like HyperNEAT. However, selective pressure for these kinds of changes might primarily arise indirectly through increased evolvability of the offspring (for a review of different ideas, see (Hansen, 2006)) and may therefore be too weak in many situations, or become effective only over time scales that are currently beyond the reach of artificial evolution.

In this article, we propose a more direct method to guide mutations towards features under active evolution, and away from previously evolved adaptive features. The basic idea is that only those parts of a neural network that were created by mutations most recently can be mutated. Older structures are frozen and cannot be mutated any more. The NEAT method has a feature that makes implementation of this approach very easy: every time a neuron or a connection arises by mutation, it receives a globally unique identification number. One simple implementation is just to take this number from a counter that is increased whenever a new number is assigned. In that case, the numbers also provide an indication of relative time. The genes in a genome can be ordered according to the time of their creation, and only a fixed number of the newest genes are then available for mutations.

This method is related to earlier approaches on incremental evolution. E.g., one method uses a new module for each new fitness function term, and may restrict mutations in the older modules (Pasemann et al., 2001). However, our approach is more fine-grained and gradual, and makes use of the identification numbers that are used in NEAT and derived methods like HyperNEAT and NEATfields. No manual definition of modules or partitioning of fitness functions is necessary. We expect that if used in combination with other recent neuroevolution techniques, the technique presented here will enable open-ended evolution and complexification of neural agents.

Open-ended evolution is an interesting concept from the perspective of both evolutionary robotics and theoretical biology. A precise measure for evolutionary activity that was introduced several years ago (Bedau et al., 1998) links open-ended evolution to the unbounded growth of cumulative evolutionary activity, which can be achieved by unlimited growth of diversity and/or unlimited complexification. An abstract model that has unbounded growth of diversity has been introduced shortly afterwards (Maley, 1999). A more complex artificial life system with unbounded evolutionary activity has also been designed (Channon, 2006). One of us has recently presented an abstract model of open-ended coevolution (Inden, 2012). In that model, the genotype and phenotype of an organism is a string of integer numbers from some bounded range. The fitness of an organism depends on the results of matching its number string against those of organisms from the other population. In many variants of the model, mutations are only performed at the end of the string. The present article aims at initiating a transfer of this approach, and the resulting open-ended evolution, to the domain of neural agent evolution.

## Methods

### The patches task

An agent resides in a two-dimensional arena where  $x$  and  $y$  coordinates are constrained to the range  $[-1, 1]$  each. At each time step, it can change its position by  $o_i \cdot 0.1$  in both

dimensions simultaneously, where  $o_i \in [-1, 1]$ ,  $i \in \{1, 2\}$ , is the respective neural network output. This means it can get from one border of the arena to the other in twenty time steps. Every twenty time steps, the position of the agent is checked. Only if it is on the correct nest site in its arena, it will survive into the next round of twenty time steps. The left nest site covers all positions with  $x \in [-1, -0.5]$ , whereas the right nest site covers all positions with  $x \in (0.5, 1]$ . A long binary random sequence is generated before evolution begins, and determines which nest site is the correct one in each round. This means that the agents basically have to learn to produce a binary random sequence by evolution. The agents get the following input: a bias input, their current position, and a number of inputs indicating the number of the current round (as detailed below).

For every successful round, a reward of 1.0 is added to the fitness. In the final (unsuccessful) round, the agent obtains an additional reward of  $\frac{1+pos_x}{4}$  if the right nest site was the correct target, or  $\frac{1-pos_x}{4}$  if the left nest site was the correct target.

It can be seen from this description that actually only one spatial dimension is directly relevant for the task. The  $y$  direction is introduced for purposes of visualization and to provide an additional neutral dimension for future more complicated tasks.

### The NEAT neuroevolution method

The NEAT (NeuroEvolution of Augmenting Topologies) method (Stanley and Miikkulainen, 2002) is a well known method for simultaneously evolving the topology and the connection weights of neural networks. It starts evolution with one of the simplest possible network topologies and proceeds by complexification of that topology. More specifically, the common ancestor of the whole population has one neuron for each output, each of which is connected to all inputs. There are no hidden neurons. Here, we start even simpler: Each output has one neuron, and each of this neurons is initially connected to 30% of the inputs on average. It has been shown previously that letting evolution select inputs for the neural network can result in superior performance if the input space is large as compared to starting with a fully connected network (Whiteson et al., 2005). Evolution then proceeds by adding neurons and connections.

Our NEAT implementation<sup>1</sup> uses mutation operators that are very similar to those of the original NEAT implementation for evolving the contents of the field elements. The most common operation is to choose a fraction of connection weights and either perturb them using a normal distribution with standard deviation 0.18, or (with a probability of

<sup>1</sup>To be more accurate, we use an implementation of the NEAT-fields method, which is an extension of NEAT that makes possible the evolution of large neural networks with regularities (Inden et al., 2012). However, all extension features are switched off, so the method is reduced to pure NEAT.

0.15) set them to a new value. The application probability of this weight changing operator is set to 1.0 minus the probabilities of all structural mutation operators, which amounts to 0.938 here. A structural mutation operator to connect previously unconnected neurons is used with probability 0.02, while an operator to insert neurons is used with probability 0.001. The latter inserts a new neuron between two connected neurons. The weight of the incoming connection to the new neuron is set to 1.0, while the weight of the outgoing connection keeps the original value. The idea behind this approach is to change the properties of the former connection as little as possible to minimize disruption of existing functional structures. The former connection is deactivated but retained in the genome where it might be reactivated by further mutations. There are two operators that can achieve this: one toggles the active flag of a connection and the other sets the flag to 1. They are used with probability 0.01 each.

Once a new gene arises by mutation, it receives a globally unique reference number. This number is generated by a global counter that is incremented every time a new gene arises. The innovation numbers are originally used by NEAT to align two genomes during the process of recombination (although in the experiments reported here, no recombination is used). They are also used to define a distance measure between networks, as will be explained in the next section.

The activation of the individual neurons is a weighted sum of the outputs of the neurons  $j \in J$  to which they are connected, and a sigmoid function is applied on the activation:  $o_i(t) = \tanh(\sum_{j \in J} w_{ij} o_j(t-1))$ . Like in some other NEAT implementations, connection weights are constrained to the range  $[-3, 3]$ . There is no explicit threshold value for the neurons. Instead, a constant bias input is available in all networks.

### Speciation selection

NEAT uses speciation selection by default. This method is fitness based, but uses some techniques to protect innovation that may arise during evolution against competition from fitter individuals that are already in the population. As a prerequisite, the globally unique reference numbers assigned to each gene are used to calculate a distance measure between two neural networks. The dissimilarity between two networks is calculated as  $d = c_r \#ref_c + c_w \sum \Delta w$ , where  $\#ref_c$  is the number of connections present in just one of these networks,  $\Delta w$  are the connection weight differences (summed over pairs of connections that are present in both networks), and the  $c$  variables are weighting constants with  $c_r = 1.0$ ,  $c_w = 1.0$  by default.

Using this dissimilarity measure, the population is partitioned into species by working through the list of individuals. An individual is compared to representative individuals of all species until the dissimilarity between it and a representative is below a certain threshold. It is then assigned to this species. If no compatible species is found, a new species

is created and the individual becomes its representative.

The number of offspring assigned to a species is proportional to its mean fitness. This rather weak selection pressure prevents a slightly superior species from taking over the whole population, and enables innovative yet currently inferior solutions to survive. In contrast, the selection pressure between members of the same species is much stronger: the worst 60% of the individuals belonging to that species are deleted, after which the other individuals are selected randomly. Species that have at least five individuals in the next generation also take the best individual into the next generation without mutations. If the maximum fitness of a species has not increased for more than 100 generations and it is not the species containing the best network, its mean fitness is multiplied by 0.01, which usually results in its extinction. Also, in order to keep the number of species in a specified range, the dissimilarity threshold is adjusted in every generation if necessary. Here, the initial speciation threshold is 4.0, the population size is 1000, and the target number of species is between 35 and 45. All numerical parameters for speciation selection have been taken over from previous experiments on other tasks (Inden et al., 2012).

Genetic speciation will be used as point of comparison for the experiments reported here, but the main method used is speciation based on behavioral criteria. This means that the distance between neural agents is not calculated from their genes, but from a metric of the behavior space. For the *patches* task, the final position  $(x, y)$  of an individual is recorded, and the distance between two individuals is just  $(x_1 - x_2)^2 + (y_1 - y_2)^2$ . The initial speciation threshold is set to 0.1. Everything else works as for genetic speciation.

Tournament selection with a tournament size of two and an elite of size 10 is also used for comparison.

### Incremental evolution of network architecture

Usually, mutations are applied on all genes with uniform probability. In contrast, the method introduced here allows mutations only on the  $c_m$  newest genes. The relative age of all genes is known because their innovation numbers are ordered by the time of their creation, so the smallest innovation number where mutations are still allowed can be calculated at the beginning of the mutation procedure from a list of all genes in the genome.  $c_m$  should obviously be greater than the number of genes in the common ancestors. For the *patches* task and the default input configuration described below, there are 18 genes in the common ancestor on average, and  $c_m$  is set to 25. The method is robust to some variation in this parameter.

All mutations are forbidden on older genes, including perturbations of the connection weights. However, connections between new and old neurons are allowed, as are split operations applied on connections from the input or to the output. The first exception makes connecting newly evolved structures with older structures possible, while the second opens

up possibilities for newer structure to be connected to inputs and outputs.

### Incremental provision of network input

For the task considered here, the agent needs to react differently in different rounds, therefore it needs to possess some information that is correlated to the number of the current round at any point in time. Given that neural networks can generate internal dynamics, they could be expected to track time entirely internally. One could also think of providing the current round as a binary number on several inputs, or provide some periodic inputs with different periods to simplify evolution of time-dependent behavior. Preliminary experiments have shown that all methods work to some degree, but not very well. Therefore, the approach chosen here is to provide an input for each round that is at 1.0 during that round, and at 0.0 at other times. That approach implies not only that the number of inputs is potentially unlimited, but also that it is growing linearly with the number of rounds.

In our NEAT implementation, the neuroevolution methods need to be provided with information on the input and output geometry by the task specific methods. For the purposes of the pure NEAT method as reported here, this information is just a list of network inputs and a list of network outputs<sup>2</sup>. Each input and output has a unique identification number just like the network genes have. This number is stored in the genome whenever a connection from input or to output is established by NEAT.

To evolve neural networks with a potentially unlimited number of inputs, three parameters have to be set in our approach. The first two are related to the task: The initial number of inputs  $c_s = 20$  and the input increment number  $c_i = 10$ . Again, the exact values are task specific and can be varied within reasonable bounds without much influence on the performance. In the initial generation,  $c_s$  inputs are presented in the task geometry. Whenever the task components relating to these inputs are solved sufficiently well, the next  $c_i$  inputs are added to the task geometry. For the purposes of the experiments here, a solution is sufficiently good if it survives at least  $n_i - c_i$  rounds, where  $n_i$  is the current number of network inputs provided. Once a sufficiently good individual is found, the number of provided inputs is increased for all individuals in the next generation.

The third parameter  $c_e = 25$  is the number of newest inputs that are considered by the mutation operator for establishing new connections. Connections to older inputs will not be established. Of course, some inputs could be made exempt from this rule if they are considered to be important for later stages of evolution as well. But this does not seem to be necessary for the task considered here.

<sup>2</sup>For the NEATfields method, the task geometry contains more information related to how the inputs and outputs are structured into fields. Details can be found in Inden et al. (2012).

Figure 1: Performance of different configurations. The configurations are denoted by combinations such as “+/+”, where the first symbol indicates the presence of the incremental network evolution technique, and the last symbol indicates the presence of the incremental input provision technique.

## Experiments and results

The first set of experiments is designed to show that the two techniques proposed here — incremental evolution of network architecture and incremental provision of network input — do indeed lead to evolutionary learning of sequences of arbitrary length if applied to the *patches* task. NEAT with both techniques is compared against NEAT with only one or none of these techniques. As Fig. 1 shows, using both techniques leads to significantly more performance than using one technique alone, which in turn is significantly better than using none of these techniques. When using both techniques, the highest fitness reached is 227.0 on average. (As for all other experiments reported here, 20 runs of 5000 generations each have been done, and significance has been established using Wilcoxon’s rank sum test in addition to estimating it from the diagrams.) More importantly, as Fig. 2 shows, evolutionary dynamics is fundamentally different for the different configurations: When using both techniques, approximately linear growth of fitness (and of behavioral complexity by implication) with a steep slope occurs. If only the network is evolved incrementally, growth is much slower, although it may be linear as well in the depicted range. If only the inputs are provided incrementally, there is fast initial growth but later convergence. If none of the techniques is used, convergence is reached at even lower values.

It is also instructive to look at the neural network resulting from the run that achieved the highest fitness (Fig. 5). This particular network is encoded by 410 genes and consists of 39 neurons and 321 active connections (On average,

Figure 2: Mean highest fitness over the course of evolution for four different configurations denoted as in Fig. 1. The ribbons around the lines show the uncertainty in the mean (standard error).

the champions of all runs had  $36.1 \pm 1.3$  neurons). It can be seen that the output for movement in the  $x$  direction is integrated at neuron 0, whereas many different neurons directly connect to the output responsible for movement in the neutral  $y$  direction. Not all inputs are connected to the network. For those that are, there is a rather regular pattern of radial spikes leading to the hidden layer of the network. However, some hidden neurons are also connected to a few older inputs. In general, the older neurons have a higher degree of connectedness. This pattern of connectivity can be interpreted as arising from a rather regular incremental evolution of structures together with some reuse of older structure.

When knocking out a single neuron at a time, the performance of the network is decreased for 23 (59%) of the neurons. This is a lower bound for the number of functional neurons in the network (more neurons could perhaps be shown to contribute to the function in experiments where multiple neurons are knocked out simultaneously). Furthermore, if neurons are ordered according to their time of creation by a mutation, an interesting pattern emerges (Fig. 3): The order of their creation is strongly correlated to the performance of the knockout network. A plausible explanation is that neurons that evolve later typically do not affect the behavior of the agents in the early rounds of the *patches* task. The structure that controls this behavior has been frozen. The specific task of those later neurons is to control behavior in the later rounds of the task.

A second set of experiments has been designed to examine the influence of different selection methods on the per-

Figure 3: Fitness of an evolved network after knockout of a single neuron each. Neurons are ordered according to the time of their evolutionary emergence. The line at the top indicates the fitness of the unaltered network.

formance. Earlier experiments have shown that solutions of sufficient quality for many tasks can only be found using particular selection methods like speciation selection or methods using novelty search (Stanley and Miikkulainen, 2002; Lehman and Stanley, 2011; Inden et al., 2013). Therefore, interesting results on representations and mutation operators could be masked if inappropriate selection methods are used. We have therefore adopted the general strategy of never just considering one aspect of neuroevolution in isolation. However, as Fig. 4 shows, performance does not differ significantly between behavior speciation and tournament selection for this task. Genetic speciation performs significantly worse than the other two methods.

## Discussion

We have claimed that neural agents can learn behavioral sequences of arbitrary length using the techniques presented here, and that this represents a step towards open-ended evolution and complexification. Evidence has been provided in the form of approximately linear growth of behavioral complexity over 5000 generations. To our knowledge, the resulting adaptive behavioral complexity is a substantial advance over previous evolutionary robotics results, where agents were trained to perform a few sequential actions only.

However, it might be argued that there is nothing to guarantee further linear growth beyond what has been empirically shown, and that there even may be some inherent limitations in the method that might eventually (though much later than usual) make evolution come to a halt. To these kinds of arguments, two replies can be made: Firstly, we may (as discussed by previous authors (Bedau et al., 1998;

Figure 4: Performance of different selection methods for the *patches* task. PhenSpec, behavioral speciation; GenSpec, genetic speciation; TS, tournament selection.

Maley, 1999)) take a rather pragmatic approach to open-endedness. Eventually, evolution will always come to a halt because of resource limits in its environment. If we have a method that seems likely to be able to reach these resource limits provided that parameters are set appropriately, this may already qualify as leading towards open-ended evolution. Secondly, we have only described a simple implementation of our ideas because this was sufficient for the simple task studied here. More sophisticated implementations might remove some remaining limitations in the method. For example, as implemented currently, it is possible to connect new neurons to arbitrary old neurons. As the number of old neurons grows by complexification, the waiting times for connections to specific neurons again increase, which may lead to a slowdown in evolution. However, one could also easily set a second age threshold and only connect to old neurons that are younger than this second threshold. Similar solutions should be possible for other mutation operators.

Here, we let the agents only learn random sequences. When their length increases, so does their algorithmic complexity, as that complexity essentially measures the randomness of a sequence (Li and Vitányi, 1997). A fundamental question around the issue of open-ended evolution, however, is whether also the complexity concerned with the structural regularities can be made to increase by such a scheme (Ay et al., 2011). This is not yet addressed by our simulations. It would clearly be interesting to provide more regular sequences and find out how well some kind of generalization can be learned on top of this sequential learning of individual instances. We think that the ideas of incremental genome growth and restriction of mutations to the most recently evolved genes can also contribute to that issue.

Figure 5: An evolved neural network that survives for 286 rounds. Inputs are displayed in the outer circle, hidden neurons in the inner circle, and outputs on the right. Connections to the output are displayed in red. Inputs and hidden neurons are in evolutionary order starting approximately at 3 o'clock and rotating clockwise from there.

One might ask to what extent open-ended complexification can be achieved in other domains using these methods. This is a question for further research. A first observation is that in the task studied here, individual parts of the task are presented sequentially (i.e., the agent only has to make a correct guess at some point in time once it has evolved to make correct guesses at all times before that time). This corresponds well with the incremental evolution of network structure enforced by our technique. It is unknown whether and under what conditions evolution can find a path for itself if the fitness function is less structured. It will also be interesting to see how well the methods work for real robots operating in more complex and noisy environments.

We also note that the presented techniques can be used with other neuroevolution methods that use unique identification numbers for genes. In fact, we have already implemented it for NEATfields and aim to combine incremental evolution with learning geometric regularities as is possible with NEATfields and some other methods.

Finally, while the presented technique might seem to be a very contrived addition to evolution, it could be argued that it is a strong simplification and an extreme case of something that does happen naturally to some degree in evolution if evolution occurs on complex genetic architectures. We have already mentioned that selection for compressed representa-

tions of individual features has been observed in an artificial life system (Ofria et al., 2003). It is also known that different regions in animal genomes are subject to different mutation rates, and that this is under genetic control (Martincorena et al., 2012). Evolution of genetic architectures has been the subject of intense research in recent decades (Hansen, 2006). Therefore, the ideas presented here for open-ended evolution and complexification may ultimately be relevant for a class of systems much wider than just neural agents.

# Spatial Organisation of Cooperation with Contingent Agent Migration

Pierre Buesser and Marco Tomassini

HEC Faculty, Information Systems Department, University of Lausanne, Switzerland

## Abstract

In the framework of game theory and cooperation, we study standard two-person population games when agents in the population are allowed to move to better positions in a two-dimensional diluted grid. We show that cooperation may thrive for small interaction radius and when mobility is low. Furthermore, we show that, even when the agents cannot change their game strategy, interesting spatial patterns do emerge as players explore their neighborhood in order to find a better place to migrate to. In the Prisoner's Dilemma and Stag-Hunt games, when the losses experienced by cooperators against defectors as well as the game and migration radius are large enough, players move in a coherent way because clusters of cooperators followed by defectors form. On the other hand, in the Hawk-Dove game or when the migration radius is small, players end up blocked into stationary clusters.

## Introduction

Systems whose parts are contained in physical space are very important in biological and social sciences since most interactions among living beings or artificial actors take place in such a space. Thus game-theoretical interactions among spatially embedded agents distributed according to a fixed structure in the plane have been studied in detail since the pioneering works of Axelrod (Axelrod, 1984) and Nowak and May (Nowak and May, 1992). The related literature is very large; see, for instance, the review article by Nowak and Sigmund (Nowak and Sigmund, 2000) and references therein for a synthesis. Most of this work was based on populations of agents arranged according to planar regular grids for mathematical simplicity and ease of numerical simulation. Recently, some extensions to more general spatial networks have been discussed in (Buesser and Tomassini, 2012). Strategic behavior on fixed spatial structures is important but, in the majority of real situations both in biology and in human societies, actors have the possibility to move around in space. Many examples can be found in biological and ecological sciences, in human populations, and in engineered systems such as ad hoc networks of mobile communicating devices or robot teams. Mobility may have positive or negative effects on cooperation, depending on several

factors. For instance, early on Enquist and Leimar (Enquist and Leimar, 1993) studied a model in which space is not explicitly represented but assortment of strategies is made non-uniform by introducing the possibility of abandoning a non-profitable relationship and searching for another partner, thus modifying the homogeneous well-mixed original population structure. Their main conclusion was that mobility may seriously restrict the evolution of cooperation. In the last decade there have been several new studies of the influence of mobility on the behavior of various games in spatial environments representing essentially two strands of research: one in which the movement of agents is seen as a random walk, and a second one in which movement may contain random elements but it is purposeful, or strategy-driven. In the present study we focus on situations where, instead of randomly diffusing, agents possess some basic cognitive abilities and they actively seek to improve their situation by moving in space represented as a discrete grid in which part of the available sites are empty and can thus be the target of the displacement. This approach has been followed, for example, in (Helbing and Yu, 2009, 2008; Jiang et al., 2010; Chen et al., 2011; Aktipis, 2004). The mechanisms invoked range from success-driven migration (Helbing and Yu, 2009), adaptive migration (Jiang et al., 2010), flocking behavior (Chen et al., 2011), and cooperators walking away from defectors (Aktipis, 2004). The general qualitative message of this work is that purposeful contingent movement may lead to highly cooperating stable or quasi-stable population states if some conditions are satisfied. Despite all the above work, the quantitative results strongly depend on the assumptions made and on the details of the models.

Our approach here is inspired by the work of (Helbing and Yu, 2008, 2009) which they call "success-driven migration" and which has been shown to be able to produce highly cooperative states. In this model, locally interacting agents playing either defection or cooperation in a two-person Prisoner's Dilemma are initially randomly distributed on a grid in equal proportions with a certain density such that there are empty grid points. Agents are updated one at a time.

When chosen for updating, the agent evaluates the current payoff she would accumulate by playing two-person games with all her current neighbors but she can also “explore” an extended square neighborhood by testing all the empty positions up to a given distance. If the player finds that it would be more profitable to move to one of these positions then she does it, choosing the best one among those tested, otherwise she stays at her current place. Helbing and Yu find that robust cooperation states may be reached by this single mechanism, even in the presence of random noise in the form of random strategy mutations and random agent relocation. Our study builds upon this work in several ways. In the first place, whilst Helbing and Yu had a single game neighborhood, we systematically investigate game neighborhood and migration neighborhood, showing that only some values of this pair of parameters allow the evolution of cooperation using success-driven migration. Second, we present systematical results for a whole game phase space including the Hawk-Dove class of games, the Stag Hunt coordination class, and the Prisoner’s Dilemma class, while only the Hawk-Dove and the Prisoner’s Dilemma are studied in Helbing and Yu (2008). We find that fully cooperative states can be reached for the standard neighborhoods and for several migration distances in the Stag Hunt case, while cooperation can also be achieved in the Prisoner’s Dilemma for a non-negligible part of its game space. Mobility is less beneficial in the hawk-dove game where cooperation levels are on the average only slightly better than in the static, motionless case. Finally, we also study the extreme case of system evolution when agents cannot change their initially attributed strategy and are only allowed to test free cells within their migration radius in order to possibly move to more profitable regions. Here cooperation cannot evolve by definition but we are interested in the dynamical patterns that may form, i.e. whether or not the agent distribution remains uniform during the dynamics. In this case, in the Prisoner’s dilemma and Stag Hunt games we find that players move in a coherent way because clusters of cooperators followed by defectors are formed. On the other hand, in the Hawk-Dove game or when the radius within which players move is small, players end up blocked into stationary clusters.

## Evolutionary Games and Migration in Two-Dimensional Space

### The Games Studied

We investigate three classical two-person, two-strategy, symmetric games classes, namely the Prisoner’s Dilemma (PD), the Hawk-Dove Game (HD), and the Stag Hunt (SH). These three games are simple metaphors for different kinds of dilemmas that arise when individual and social interests collide. The Harmony game (H) is included for completeness but it is not a dilemma since cooperation is trivially the NE. The main features of these games are summarized here

for completeness; more detailed accounts can be found elsewhere e.g. (Weibull, 1995; Hofbauer and Sigmund, 1998; Vega-Redondo, 2003). The games have the generic payoff matrix  $M$  (equation 1) which refers to the payoffs of the row player. The payoff matrix for the column player is simply the transpose  $M^T$  since the game is symmetric.

$$\begin{array}{cc} & \begin{array}{cc} C & D \end{array} \\ \begin{array}{c} C \\ D \end{array} & \begin{pmatrix} R & S \\ T & P \end{pmatrix} \end{array} \quad (1)$$

The set of strategies is  $\Lambda = \{C, D\}$ , where  $C$  stands for “cooperation” and  $D$  means “defection”. In the payoff matrix  $R$  stands for the *reward* the two players receive if they both cooperate,  $P$  is the *punishment* if they both defect, and  $T$  is the *temptation*, i.e. the payoff that a player receives if he defects while the other cooperates getting the *sucker’s payoff*  $S$ .

In order to study the usual standard parameter space (Santos et al., 2006; Roca et al., 2009), we restrict the payoff values in the following way:  $R = 1$ ,  $P = 0$ ,  $-1 \leq S \leq 1$ , and  $0 \leq T \leq 2$ .

For the PD, the payoff values are ordered such that  $T > R > P > S$ . Defection is always the best rational individual choice, so that  $(D, D)$  is the unique Nash Equilibrium (NE) and also the only fixed point of the replicator dynamics (Weibull, 1995; Hofbauer and Sigmund, 1998). Mutual cooperation would be socially preferable but  $C$  is strongly dominated by  $D$ .

In the HD game, the order of  $P$  and  $S$  is reversed, yielding  $T > R > S > P$ . Thus, when both players defect they each get the lowest payoff. Players have a strong incentive to play  $D$ , which is harmful for both parties if the outcome produced happens to be  $(D, D)$ .  $(C, D)$  and  $(D, C)$  are NE of the game in pure strategies. There is a third equilibrium in mixed strategies which is the only dynamically stable equilibrium (Weibull, 1995; Hofbauer and Sigmund, 1998).

In the SH game, the ordering is  $R > T > P > S$ , which means that mutual cooperation  $(C, C)$  is the best outcome and a NE. The second NE, where both players defect is less efficient but also less risky. The difficulty is represented by the fact that the socially preferable coordinated equilibrium  $(C, C)$  might be missed for “fear” that the other player will play  $D$  instead. The third mixed-strategy NE in the game is evolutionarily unstable (Weibull, 1995; Hofbauer and Sigmund, 1998).

Finally, in the H game  $R > S > T > P$  or  $R > T > S > P$ . In this case  $C$  strongly dominates  $D$  and the trivial unique NE is  $(C, C)$ . The game is non-conflictual by definition and does not cause any dilemma, it is mentioned to complete the quadrants of the parameter space.

There is an infinite number of games of each type since any positive affine transformation of the payoff matrix leaves the NE set invariant (Weibull, 1995). Here we study the customary standard parameter space (Santos et al., 2006; Roca

et al., 2009), by fixing the payoff values in the following way:  $R = 1$ ,  $P = 0$ ,  $-1 \leq S \leq 1$ , and  $0 \leq T \leq 2$ .

In the  $TS$ -plane each game class corresponds to a different quadrant depending on the above ordering of the payoffs as depicted in Fig 1, left image, and the figures that follow. The right part of Fig 1 shows the standard replicator dynamics results for a well mixed population (Weibull, 1995).

### Population Structure

The euclidean two-dimensional space is modeled by a discrete square lattice of side  $L$  with toroidal borders. Each vertex of the lattice can be occupied by one player or be empty. The *density* is  $\rho = N/L^2$ , where  $N \leq L^2$  is the number of players. Players can interact with  $k$  neighbors which lie at a distance smaller or equal than a given constant  $R_g$ . Players can also migrate to empty grid points at a distance smaller than  $R_m$ . The relationships between the neighborhoods defined as above and the customary square Moore neighborhoods of increasing order are illustrated in Fig. 2.

### Payoff Calculation and Strategy Update Rules

Here it is specified how individual's payoffs are computed and how agents decide to revise their current strategy. We take into account that each agent  $i$  interacts locally with a set of neighbors  $V_i$  lying closer than  $R_g$ . Let  $\sigma_i(t)$  be a vector giving the strategy profile at time  $t$  with  $C = (1, 0)$  and  $D = (0, 1)$  and let  $M$  be the payoff matrix of the game (equation 1). The quantity

$$\Pi_i(t) = \sum_{j \in V_i} \sigma_i(t) M \sigma_j^\top(t) \quad (2)$$

is the cumulated payoff collected by player  $i$  at time step  $t$ .

We use an asynchronous scheme for strategy update and migration, i.e. players are updated one by one by choosing a random player in each step with uniform probability and with replacement. Then the player migrates with probability  $p$  or updates its strategy with probability  $1 - p$ . Several update rules are customary in evolutionary game theory (Roca et al., 2009). Here we shall use imitative strategy update protocol which consists in switching to the strategy of the neighbor that has scored best in the last time step. This *imitation of the best* (IB) policy can be described in the following way: the strategy  $\sigma_i(t)$  of individual  $i$  at time step  $t$  will be

$$\sigma_i(t) = \sigma_j(t-1), \quad (3)$$

where

$$j \in \{V_i \cup i\} \text{ s.t. } \Pi_j = \max_{k \in \{V_i \cup i\}} \{\Pi_k(t-1)\}. \quad (4)$$

That is, individual  $i$  will adopt the strategy of the player with the highest payoff among its neighbors including itself. If there is a tie, the winner individual is chosen uniformly at random.

A final remark is in order here. The above model rules are common in numerical simulation work, which has the advantage that the mathematics is simpler and results can be compared with previous work. However, they are homogeneous among the agents and there is no learning. It is far from clear whether they are able to model real situations in biological systems and especially human societies. However, we feel that these considerations are outside the scope of the present numerical investigation.

### Strategy Imitation and Migration rules

When player  $i$  is chosen for update, she changes her strategy with probability  $1 - p$  or migrates with probability  $p$ . If the pseudo-random number drawn dictates that  $i$  should migrate, then she considers  $N_{test}$  randomly chosen positions in the disc of radius  $R_m$  around itself in order to take into account her bounded rationality.  $N_{test} = 20$  has been used in all the simulations. For each trial position the player computes the payoff that she would obtain in that place with her current strategy. The positions already occupied are just discarded from the possible choices. Then player  $i$  stays at her current position if she obtains there the highest payoff, or migrates to the most profitable position among those explored during the test phase. If several positions, including her current one, share the highest payoff she chooses one at random. The protocol described in Helbing and Yu (Helbing and Yu, 2009) is slightly different: the chosen player chooses the strategy of the best neighbor including himself with probability  $1 - r$ , and with probability  $r$  his strategy is randomly reset. Before this imitation step  $i$  deterministically chooses the highest payoff free position in a square neighborhood surrounding the current player and including himself. If several positions provide the same expected payoff, the one that is closer to the old position of  $i$  is selected.

---

#### Algorithm 1: migration of player $i$

---

```

for  $j \in [1, N_{test}]$  do
    choose random position  $x_j$  in  $V_i$ 
    if  $x_j$  is free then
        compute the expected payoff  $\Pi(x_j)$  of player  $i$ 
        at  $x_j$ 
    choose the best  $\Pi(x_j)$ ; if several  $x_j$  share the same
     $\Pi(x_j)$  choose one at random and migrate to this
    position
    
```

### Mobility Measure

In order to assess if a player has a definite direction of motion with respect to time we will use the following mobility measure. Mobility is defined as  $M = \max_{t \in [0, \tau]} (D_t) / L$  where  $\tau$  is the time interval for a player to travel a total distance  $L$  if she moves the maximal distance  $R_m$  at each time step in the same direction.  $D_t$  is the Euclidean distance from

Figure 1: (Color online) Left image: The games phase space (H= Harmony, HD = Hawk-Dove, PD = Prisoner's Dilemma, and SH = Stag Hunt) as a function of  $S, T$  ( $R = 1, P = 0$ ). Right image: cooperation at steady state in a well mixed population for comparison purposes. Lighter tones stand for more cooperation. Figures in parentheses next to each quadrant indicate average cooperation in the corresponding game space.

Figure 2: Relationships between the neighborhoods defined by the radii  $R_g$  and  $R_m$  and the Moore square neighborhoods. Left: with the 1.5 radius the neighborhood is identical with the standard Moore neighborhood at distance one. Middle: radius 3 is almost equivalent to a Moore neighborhood at distance two marked as a square. Right: with radius 5 the closer Moore neighborhood has distance four.

the initial position to the position at time  $t$ . The interval  $\tau$  is not taken from the beginning of the simulation but rather after a time sufficient for the mobile patterns to form. Thus  $M$  measures the ratio between the maximal distance over time reached by a player from her initial position and the maximal distance that it is possible to reach in the best case. We multiplied this measure by four in order to increase the contrast in the images. However, this measure is not a strict indicator of coherent motion as moving clusters can collide and change direction.

### Simulation Parameters

The  $TS$ -plane has been sampled with a grid step of 0.1 and each value in the phase space reported in the figures is the average of 50 independent runs. The evolution proceeds by first initializing the population by creating a player in each cell of the underlying lattice with probability  $\rho$ . Then the players' strategies are initialized uniformly at random such that each strategy has a fraction of approximately  $1/2$  unless otherwise stated. For each grid point, agents in the popula-

tion are chosen sequentially at random with replacement to revise their strategies or positions. Payoffs are constantly updated. To avoid transient states, we let the system evolve for a period of  $\tau = 1000$  time steps, for each time step  $N = 1000$  players are chosen for update. At this point almost always the system reaches a steady state in which the frequency of cooperators is stable except for small statistical fluctuations. We then let the system evolve for 50 further steps and take the average cooperation value, or the mobility, in this interval. We repeat the whole process 50 times for each grid point and, finally, we report the average cooperation values over those 50 repetitions.

## Results

### Strategy Evolution and Mobility

In this section we discuss cooperation results with the IB rule and adaptive migration and explore the influence of different radii  $R_m$  and  $R_g$  and the density  $\rho$ . Fig. 3 left image displays the cooperation level in the  $ST$ -planes with the

Figure 3: (Color online) Average cooperation levels with IB strategy revision rule as a function of  $R_g$  and  $R_m$  with  $p = 0.5$  and  $\rho = 0.5$ . Left image: Random migration. Right image: best fitness migration rule. The size of the population is 1000 players. In all cases the initial fraction of cooperators is 0.5 randomly distributed among the occupied grid points.

Figure 4: (Color online) Average cooperation levels with IB strategy revision rule as a function of  $R_g$  and  $R_m$  with  $p = 0.5$  and  $\rho = 0.1$ . Left image: Random migration. Second image: best fitness migration rule. The size of the population is 1000 players. In all cases the initial fraction of cooperators is 0.5 randomly distributed among the occupied grid points.

IB rule and a density  $\rho = 0.5$  for several combinations of  $R_g$  and  $R_m$ . For the sake of comparison, and in order to have a baseline case, Fig. 3 left image shows the case in which migration is not dictated by success but, rather, it is simply random, i.e. the target of migration will be a free cell randomly drawn among those contained in the  $R_m$  disk. The right image depicts cooperation levels when migration is success-driven. We see that, for  $R_g = 1.5$ , full cooperation is achieved in the SH quadrant for all  $R_m$  in the case of contingent migration while cooperation is notably lower in the random migration case for all  $R_m$ . For the PD cooperation remains nearly constant through  $R_m$  for  $R_g = 1.5$ , or slightly improves with smaller  $R_m$  in the contingent migration case with average values in the quadrant of about 0.3. In contrast, it is almost zero in the random diffusion case. Increasing the game radius  $R_g$  doesn't help and all average values tend to fall independent of  $R_m$ . This is because enlarging the neighborhood of a player is a step towards the mixed population in which cooperation results are worse, as can be seen in Fig. 1. We have observed that the increase in cooperation for  $R_g = 1.5$  with “intelligent” migra-

tion is essentially due to the formation of cooperator clusters that remain relatively stable throughout evolution thanks to the possibility for cooperators to join one of those clusters. With larger  $R_g$  values, small cooperator clusters are easier to break and large  $C$  clusters, which would help cooperation to establish itself in the cluster, cannot form and defection prevails at least in the PD case. The Hawk-Dove game, due to its mixed-strategy equilibrium benefits less from success-driven migration as the two other games.

Density is a parameter that heavily influences the evolution of cooperation Vainstein et al. (2007); Sicardi et al. (2009), also in the presence of intelligent migration Helbing and Yu (2009); Jiang et al. (2010). Too high densities are detrimental because they tend to limit the mobility of agents to a point that only cooperator clusters that appear owing to statistical fluctuations in the initial population compositions can eventually remain stable. It appears that low and intermediate densities give more freedom to the population for moving around and to search for better positions. Figure 4 right image shows average cooperation results for the IB strategy revision rule and the same combinations of radii

Figure 5: (Color online) Left: average mobility levels in the ST-plane as a function of  $R_g$  and  $R_m$ . Right: mobility in the SP-plane for  $T = 1$ ,  $R_m = 10$  and  $R_g = 10$ . The best fitness migration rule is used. The size of the population is 1000 players and  $\rho = 0.1$ . Cooperators fraction is 0.5 randomly distributed among the population. Lighter tones stand for more mobility.

but for  $\rho = 0.1$  instead of 0.5. With  $\rho = 0.1$  cooperation generally increases. In this case defectors attack clusters with a smaller rate since they are more diffused in space and move randomly until they find a cluster of cooperators. The advantage of intelligent migration with respect to random motion is even more marked here by comparing with the left image. In the latter defection appears to be even stronger than in the mixed population, but this is rather special and is due to the fact that the system is very diluted which causes most encounters to be between just two players.

### Mobility Only: Emergence of Dynamic Clusters

In this section we study the emergence of dynamic clusters. These clusters are formed by a cohesive group of cooperators followed by defectors. The left image of Fig. 5 displays the mobility of nodes (see Sect. 5) for several ST-planes as a function of the game and migration radius. Lighter tones stand for higher mobility and indicate that such dynamic clusters may form. It can be observed that the dynamic clusters tend to appear with low  $S$ . The horizontal stripes of constant  $M$  can be explained by the fact that, as long as  $P = 0$ , all positive values of  $T$  are identical since the best target position for migration remains the same. On the other hand, when  $P$  is comparable to  $T$  or larger, defectors form clusters among themselves and stop following cooperators, which causes  $M$  to decrease. In contrast, when  $P$  is negative enough, defectors repel each other and they can not gather behind cooperators. These effects are reflected in the averages shown in the right image of Fig. 5.

We display dynamic clusters for some particular runs in Figs. 6 and 7. Figure 6 shows clusters that have formed after a number of time steps and that are already stable as a function of  $S$  with  $R_g = 5$  and  $R_m = 10$ . The corresponding game can be inferred from Fig. 5 left image. From left to right the images show situations with increasing cluster mobility. There is a sort of mobility transition such that,

while the first two images show clusters that do not move, the rightmost one corresponds to a situation in which the clusters are much more dynamical.

Figure 7 shows the clusters appearance when mobility is high (compare with Fig. 5 left image) as a function of the radius of play  $R_g$  for the same game as above, which is in the PD region. One can see that there is a direct relationship between increasing  $R_g$  and the cluster size. With a given  $R_m$ , which is here 10, when  $R_g$  is comparatively small, clusters do form but they are continuously destroyed and reformed in an other places without a definite motion.

**The Effect of Strategy Update** In the limiting case  $p \rightarrow 1$ , i.e. very little strategy update with respect to migration, dynamical patterns form before any significant strategy update. Fig. 8 displays the ST-plane in that case. It can be observed that cooperation is lost for the lower values of  $S$ . This loss of cooperation can be related to an increase in mobility by comparing Fig. 4 (right) with Fig. 8 and by remarking that the loss of cooperation between these two cases correspond to the relatively high levels of mobility seen in Fig. 5 for this area of the game space. In the case  $p = 0.5$  the dynamical patterns cannot fully form since the strategy evolution is too fast. In fact as clusters of cooperators form defectors are attracted towards them. Considering only the case in which cooperation thrives, if  $p$  is high enough the incoming defectors are transformed into cooperators directly while approaching the cluster. Thus the cluster remains static and grows. On the other hand, when  $p$  is small the migrating defectors cumulated around the cluster will eventually cause it to move.

### Conclusion

In the framework of game theory we have studied the evolution of cooperation in spatially structured populations when a given focal player can only interact with players contained

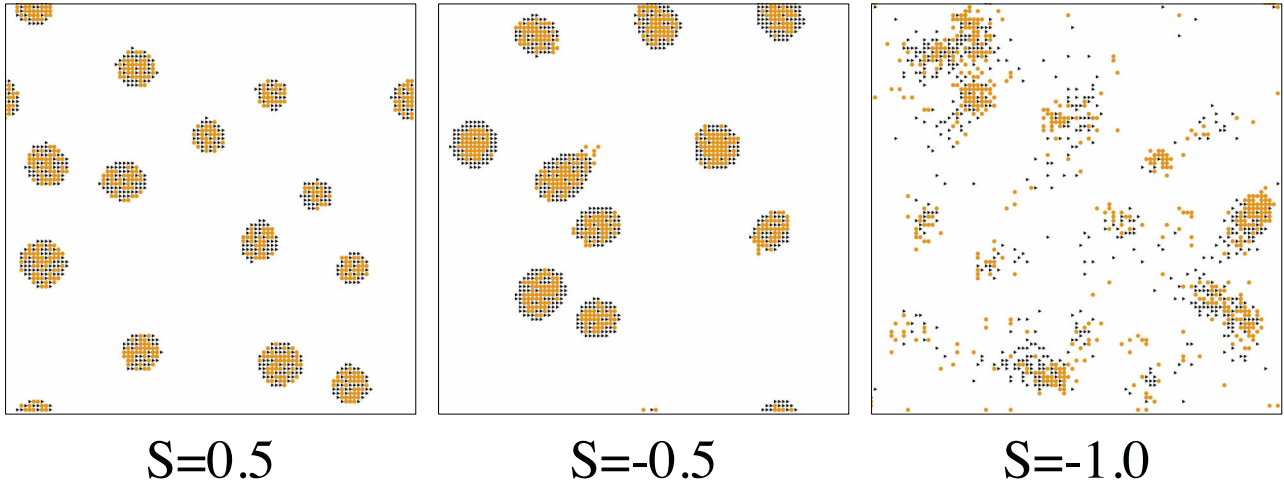

Figure 6: (Color online) Cluster for  $R_g = 5$  and  $R_m = 10$ ,  $T = 1.5$ . Cooperators are represented as orange circles and defectors as black triangles.

Figure 7: (Color online) Cluster for  $R_m = 10$ ,  $T = 1.5$ ,  $S = -1.0$  for different  $R_g$  values. Cooperators are represented in orange and defectors in black.

in a radius  $R_g$  centered on the focal player that is small with respect to the space available. This locality of interactions is a realistic feature of actual populations and markedly differs from the customary well mixed population. Besides being able to adapt their strategy with probability  $p$ , in our model players can also move around to unoccupied places in the underlying two-dimensional grid also with probability  $1 - p$ . The amount of displacement is determined by the migration radius  $R_m$ . Migration depends on the payoff, i.e. a player that has decided to migrate can examine a number of free positions around it within the radius  $R_m$ , earn a potential payoff by fictitious play with the neighbors at that position, and finally choose to migrate to the position that provides the best payoff among those tested. We show that an equal amount of this strategy and of strategy mutation in the original position gives rise to full cooperation in the SH game

space and, to comparatively high values in the more difficult PD game space. This is particularly striking when compared with the baseline case in which strategy revision is identical but migration is to a randomly chosen free cell in the disk of radius  $R_m$ .

We have also investigated pattern formation in the population under the effects of intelligent migration only. In this case too we start from a 50 – 50 random distribution of cooperators and defectors. However, now cooperation cannot evolve since strategy changes are not allowed. What we do observe is a very interesting and intricate phenomenon of dynamical or almost static pattern formation that is related to the underlying game played and that also depends on the  $R_g$  and  $R_m$  radii. We have analyzed the nature and dynamics of these clusters and we have shown that mobility of agents can be high when the sucker payoffs  $S$  reaches negative enough

Figure 8: (Color online) Average cooperation levels with best fitness migration rule and IB strategy update rule as a function of  $R_g$  and  $R_m$ ,  $\rho = 0.1$ , and  $p = 0.99$ . The size of the population is 1000 players. The initial fraction of cooperators is 0.5 randomly distributed among the occupied grid points.

values compared to the reward payoff  $R$ . The temptation  $T$  has only to be positive as the punishment  $P$  is null in our settings. For high interaction radius  $R_g$  and migration radius  $R_m$  the motion is coherent and the cooperators tend to gather and move in the same direction with swarms of defectors following them. When  $R_m$  is small players can be blocked into clusters. On the other hand, when  $R_g$  is low and  $R_m$  high the clusters are constantly destroyed and reformed in different places. For both  $R_g$  and  $R_m$  low small clusters are formed and the motion is not definite. Future work should include the study of the effect of strategy update and mobility noise in the dynamics, as well as the use of different strategy update and, possibly, migration rules.

### Abstract

Plasmids are an integral and essential factor in microbial biology and evolution, with broad implications ranging from antibiotic resistance to research tools. Much has been done to describe, quantify, and modify properties of transferable plasmids, including the extensive theoretical work using simulations and models. However, a wide gap between theory and experiments still remains, especially relating to the underlying genetic architecture of transfer as well as coevolutionary dynamics of the plasmid infectivity and susceptibility. Large-scale genomic studies and more biologically accurate models are among different approaches working towards narrowing this gap. Here we describe how *Aevol*, a digital evolution system, can be effectively used to study plasmid and quantify various aspects of their evolution and its outcomes. Specifically, we find that plasmid maintenance is extremely sensitive to the direct fitness cost of expressing transfer genes. In our study, the genes for donor ability and recipient immunity (which additively describe the probability of plasmid transfer) typically, but not exclusively, evolved on the plasmid itself. Additionally, we find epistatic interactions between genes on plasmids and the chromosome may evolve, a new aspect of their interaction and struggle for control over each other. There is a strong coevolutionary link between donor ability and recipient immunity, with their values tracking and being driven by one another. While plasmids seem to largely behave as selfish genetic elements, they occasionally may also carry metabolic genes and directly increase individual's fitness. With a number of concise questions and results, this initial study of plasmids in *Aevol* establishes the baseline and opens possibilities for future work, while simultaneously uncovering and describing novel evolutionary trajectories taken by the transferable genetic elements.

### Introduction and Background

Horizontal gene transfer in general, and plasmid conjugation in particular, have been identified as major mechanisms in microbial evolution (Ochman et al. 2000; Koonin and Wolf 2012). Better understanding of the movement of the genetic material between different species has fundamentally changed how we view and analyze phylogeny of life (Doolittle 1999; Koonin et al. 2001; Ragan et al. 2009). In parallel, plasmids have been the focus of extensive research due to their role in acquisition, maintenance, and transfer of antibiotic resistance (Davison 1999; Alekshun and Levy 2007; Bennett 2008). They have also been harnessed as a powerful tool in molecular biology, enabling research ranging from creation of

synthetic genes and gene therapy to design of pet glow-in-the-dark fish (Cohen et al. 1973; Sambrook et al. 1989; Pray 2008; Constante et al. 2011). From suicide plasmids to plasmid addiction, these transferable bits of DNA hold seemingly inexhaustible diversity of strategies for spread and survival, making them an intriguing and fascinating subject of research (Lipps 2009).

Given their spread and importance in the natural world, it is no great surprise that plasmid biology has been extensively modeled over the past decades, primarily with analytical models using differential equations (Stewart and Levin 1977; Levin and Stewart 1980; Bergstrom et al. 2000). One of the main limitations of such models rests in their lack of spatial structure – organisms interact with each other at random and cannot preferentially associate with each other. More recent work has addressed these issues by simulating the spatial dynamics of plasmids on lattices (Krone et al. 2007) and cellular automaton-like graphs (Connelly et al. 2011). However, in all of these studies, the individuals were just a collection of numerical parameters such as their plasmid susceptibility, birth or death rate, but did not have a genome and were thus not well suitable for understanding potentially important consequences of the genetic architecture of plasmid conjugation. Previous models were unable to consider the location of the plasmid transfer genes, how they may move between the plasmid and the chromosome, or interact depending on their location, which we remedy here.

Classically, plasmids can be placed into two distinct categories, based on their ability to transfer themselves from one individual to another: the conjugative plasmids, which carry the genes enabling the transfer themselves, and mobilizable plasmids, which require other means, such as genes located on other plasmids. Rather than focus on one or the other type, in our research system we give the transfer genes the opportunity to evolve on either the main chromosome or the plasmid, as well as to be freely exchanged between the two. Additionally, our digital plasmids can carry both metabolic and transfer genes and thus effectively control their horizontal and vertical transmission by modifying infectivity or directly changing the host's fitness advantage in the population. In a series of experiments presented here, we evolve and analyze hundreds of populations for thousands of generations and are able to characterize the diversity of evolutionary strategies for the location and effect of genes controlling the *in silico* plasmid transfer.

## Methods

To study plasmid dynamics and evolution we use *Aevol*, digital experimental platform that enables us to maintain, track, and manipulate large populations of digital organisms over thousands of generations. *Aevol* is similar to and builds on the success of the existing digital experimental systems, such as Avida (Lenski et al. 1999; Misevic et al. 2004, 2006; Goldsby et al. 2012). However, it also includes significant changes, particularly pertaining to more biologically realistic genetic encoding and genotype-phenotype mapping (Knibbe et al. 2006; Knibbe et al. 2007; Knibbe et al. 2008; Beslon et al. 2010). *Aevol* is freely available for download at [www.aevol.fr](http://www.aevol.fr). In all our experiments we used the default parameters unless otherwise noted. Main properties of *Aevol* have been described in great detail previously (Parsons et al. 2010; Misevic et al. 2012), so here we focus on the features specifically implemented and directly relevant for our study of the plasmids evolutionary dynamics.

### The Aevol experimental system

#### General properties.

*Aevol* individuals are double stranded binary strings, typically thousands of base pairs long. An evolved organism contains multiple proteins, flanked by promoters, terminators, and start/stop codons. During its lifetime, digital genomes undergo a microbial genetic inspired transcription and translation steps to determine the their phenotype and in turn organisms' fitness. The phenotype is the collection of proteins, each an abstract entity, physically represented by a triangle located on the phenotypic axis. The phenotypic axis is the collection of all possible traits that may be a part of the organism's phenotype, each trait corresponding to a real number between 0 and 1. Two traits that are next to each other on the phenotypic axis are more likely to interact pleiotropically, as there is a higher chance that a single protein would affect them both, than two traits located further away. Two different sequences may encode for the same gene but the traits that are close to each other on the phenotypic axis are not necessarily encoded by genes with high sequence similarity. Each protein triangle has three properties: (1) the location on the phenotypic axis that signifies the trait it primarily affects, (2) the height that represents its expression level, and (3) the width that shows the range of neighboring traits it also affects.

For any specific experimental environment, there exists a single, constant target phenotype, which is a collection of trait expression levels that are most optimal for this environment and are the target for selection. The fitness of an individual is calculated as the difference between the target function and the phenotype, and intuitively represents the percentage of the area under the target phenotype function that is covered by the phenotype. The fitness can theoretically be negative, for example for individuals that express proteins with optimal levels of zero, but such individuals are rare and are quickly selected out of the population.

**Population structure:** The default *Aevol* populations do not have an explicit structure and are akin to well-mixed bacterial populations living in liquid media. However, as spatial structure is thought to play an important role in plasmid transfer (Krone et al. 2007), we are using the square grid

structure originally implemented for the study of cooperation (Misevic et al. 2012). We can vary the strength of spatial structure using a migration parameter (*mig*), which determines the number of swaps that happen at every generation. For each swap we choose at random a pair of organisms in the population and exchange their location. High *mig* (on the order of population size) thus corresponds to a well-mixed population, while a low one (*mig* = 0) a perfectly spatially structured one.

**Mutations, selection, and reproduction:** The genome of a new organism may be different from its parent due to mutations, the errors made during replication. Specifically, organisms experience small mutations (point mutations and insertion/deletions of sequences up to 6 base pairs) as well as large mutations (duplications/deletions of more than 6bp, translocations and inversions). *Aevol* is a synchronous evolutionary model, so the fitness of all individuals is evaluated at the same time, just prior to selection. Each organism competes with neighbors from the classical 3x3 Moore neighborhood around it for a chance to place its offspring in the next generation. The offspring is chosen using roulette selection on the probabilities derived from fitness of all the individuals in the neighborhood. Each individual has a  $(a - 1) \times a^{9-R} / (a^9 - 1)$  probability of reproducing into the central position of the neighborhood, where *R* is the organism's fitness-based rank and *a* is the population-level selection pressure constant. We should note that while the phenotypic target is fixed during each experiment, the effective strength of selection does not necessarily decrease or plateau. As target expression levels are real numbers and the selection we use is rank-based, even the smallest differences in fitness will be selected for, leading to continual adaptation, if not a truly open-ended evolution. Following selection, all individuals are reproduced simultaneously, with mutations, and placed into the population.

#### Plasmids in Aevol

The most fundamental property of *Aevol* plasmids is that they are treated as genetic units, equivalent to the already existing chromosome in all but one aspects of their digital biology. They mutate at the same rate as the chromosome, are transferred vertically to the offspring during reproduction, and the genes encoded on the plasmid are combined with the chromosomal genes to form the organism's phenotype. For large mutations, for example transposition, the beginning and the end of the transposed segment, as well as the location where it will be inserted, are chosen at random from the combined length of the chromosome and plasmid. As only the beginning and the end, but not the insertion location of the transposon, must be on the same genetic unit, this mutational mechanism allows for genes to freely move between the genetic units.

The exception from the equality between the chromosome and the plasmid is, of course, that plasmids are mobile genetic elements and may also transfer horizontally, between neighboring individuals in the same generation, while chromosomes cannot do so. Both plasmids and chromosomes are capable of controlling the rate of this transfer, inspired by bacterial conjugation, by evolving genes to decrease or increase the probability of sending or receiving a plasmid.

*Donor ability and recipient immunity:* In order for individuals to be able to control the rate of plasmid conjugation, we split the phenotypic axis into three sections: metabolism, donating, and receiving. The proteins located on the metabolism section of the axis directly affect the fitness, based on how closely they match the target phenotype, as they do on the single-section axis in classical *Aevol* experiments. The proteins on the donating or receiving sections determine the organism's donor and recipient ability. The donor ability corresponds to the effort that the organism will exert in order to transfer the plasmid. Inversely, the recipient ability, which we will refer to as plasmid exclusion ability or immunity, corresponds to the effort that an individual will put into not accepting the plasmid being sent to it. Both are calculated analogously to the metabolic fitness and represent the percentage of area under the target curve in the appropriate axis section that is covered by the protein triangles. Ancestral organism has no proteins associated with plasmid transfer, but they can appear via random mutations, spread due to positive, or be eliminated via negative selection.

*Plasmid conjugation:* Plasmid transfer in *Aevol* may happen only between individuals that share the same 3x3 Moore neighborhood. At every generation, all individuals have a chance to transfer their plasmid. A given, focal organism, is first queried for its donor ability. The probability of transfer to each of the neighboring individuals is equal to the difference between focal individual's donor ability and the chosen neighboring individual's recipient immunity. If the recipient immunity is greater than the plasmid sender's donor ability, the transfer will not happen. When plasmid is transferred, a copy of the plasmid from the donor is made and it replaces the plasmid that is located in the recipient. As with other population level processes in *Aevol*, all individuals attempt to transfer their plasmids simultaneously. However, as the conjugation algorithm is necessarily executed sequentially, we must avoid giving a higher chance to individuals and plasmids that transfer first then to ones whose plasmids may have already been replaced by the time they try to transfer them. To do so, we randomize the order at which individuals attempt to transfer their plasmid at every generation. Finally, in nature there are examples of retrotransfer, where plasmid recipient also transfers genetic material back to the donor (Sia et al. 1996; Szpirer et al. 1999). Inspired by this, we included a parameter that specifies whether populations evolve with unidirectional (plasmid replacement) or bidirectional (plasmid swap) conjugation mechanism.

In the majority of our experiments, the organisms did not pay any direct cost for expressing the genes for plasmid transfer, the same way they do not pay any explicit cost for expressing metabolic genes. However, in nature, pili and other conjugation-related machinery is not only costly to produce but may also have a detrimental effect as it serves as a target for phage attachment (Smillie et al. 2010), so we added a fitness cost for expression of the donor/recipient genes, proportional to the donor/recipient ability they confer. We should stress that this is not a cost of transfer, as it affects the fitness no matter whether the plasmid transfer successfully happens or not.

*Plasmid copy number and loss:* For the ease of implementation, data collection and analysis, we assume that all individuals in *Aevol* have a single plasmid. Examining the

effects of plasmid copy number would certainly be interesting, but remains as a potential topic of future studies. Similarly, we chose not to directly model plasmid loss, but individuals still may effectively lose their plasmid by drastically decreasing its size. The smallest gene in *Aevol* requires at least 48 base-pairs, which includes 22bp-long promoter, 6bp Shine-Dalgarno sequence, 4bp Shine-Dalgarno spacer, start codon, three codons determining the width, height, and mean of the protein triangle, stop codon (all codons are 3bp long), and 11bp reverse-complement terminator sequence. Thus, while technically plasmids cannot be entirely lost in *Aevol*, the organisms can evolve to not use and effectively eliminate them.

We conclude the description of *Aevol* and its the genetic algorithm heuristic by recounting the events that occur during a single generation of evolution: (1) organisms' fitness is evaluated, based on their metabolic proteins, (2) organisms that will reproduce are selected based on their fitness, (3) mutations are applied to the new-born organisms, (4) organisms migrate, by exchanging places with a randomly chosen individual, (5) plasmids are transferred between pairs of neighboring individuals, based on their donor ability and recipient immunity, followed by the start of the next generation and return to first event in the cycle. Using this setup throughout our experiments we are able to study the dynamics of plasmid conjugation in *Aevol* over thousands of generations of evolution.

### Experimental design

Given the number of parameters relevant for plasmid transfer that can potentially be varied in *Aevol*, it is computationally nonpermissive to examine all possible combinations in any type of a factorial experimental design. Instead, we first focus on the interaction of plasmid conjugation and population structure. To do so, we performed experiments in which we set the rate of migration to 0, 100, 300, or 1000. In these experiments, the organisms did not pay any direct cost of expressing the donating or receiving genes. In the second set of experiments, we had no migration, but varied the cost of transfer instead, from 0 to 0.03, 0.1, or 0.3. To evaluate the interaction between the donor and recipient abilities, and potential coevolutionary dynamics, we also ran experiments in which either donor or recipient ability was not allowed to evolve. In particular, we set the extrinsic, constant probability of plasmid donation to 1, 0.3, 0.1, or 0.01 for all individuals, but made any genes on the donor part of the phenotypic axis act as neutral and not have any effect on fitness or donor ability. Alternatively, we set the default probability of transfer to 0 and made recipient genes act as neutral ones, allowing only for the evolution of donor ability. Finally, we conducted experiments in which the plasmid transfer was not unidirectional and instead of the invading plasmid replacing the resident one, the plasmids from the two individuals swapped places.

For each set of parameters we performed 20 replicate experiments by evolving populations of 1024 individuals for 20,000 generations. The replicate populations were started with a randomly generated ancestor containing a single metabolic gene. Each population was associated with a different seed for the random number generator, which governs all stochastic processes during evolution. All

populations shared the same phenotypic target function, specified by the arithmetic sum of six Gaussian functions of the form  $y = H \exp(-(x - M)^2 / (2W^2))$ , where  $(H, M, W) = \{(0.25, 0.15, 0.04), (0.35, 0.2, 0.02), (0.35, 0.45, 0.02), (0.25, 0.5, 0.04), (0.35, 0.8, 0.02), (0.25, 0.85, 0.04)\}$ . First pair of functions is located on the metabolism part of the phenotypic axis, while the second and third pairs are on the donating and receiving sections, respectively. The three sections of the axis are equal in length. The mutation rate per base-pair was  $2.5 \times 10^{-5}$  for all small and  $2.5 \times 10^{-6}$  for all large mutations. Selection pressure constant was  $\alpha = 0.7$ ;

At each generation, we recorded the average values for fitness, genome length, donor ability and recipient immunity in the population. Additionally, we recorded each of these values not only for the entire organism, but also for individual genetic units separately. For example, for an individual we would calculate the donor ability it would have if it contained only the plasmid or only the chromosome. All the statistical analysis was performed using Matlab R2012b.

## Results and discussion

### Plasmids and migration

In the first set of experiments we studied the effect of population structure on the evolution of plasmid transfer. Our expectation was that higher donor ability, and thus higher rate of transfer, would evolve in populations with no migration. Specifically, we thought that in the competition between donor ability and recipient immunity genes, the former would be favored in spatially structured populations by clustering together individuals that transfer genes to each other and thus decreasing the probability of negative interaction between imported and resident genes. The data in part did not support

**Figure 1. Effect of population structure on donor ability and recipient immunity of plasmid transfer.** Each line is an average value for (a) donor ability and (b) recipient immunity across 20 replicate populations that evolved for 20,000 generations with the same set of parameters, but a different random number seed. Different colors represent different migration rates (the number of organisms pairs that get swapped at each generation, 0, 100, 300, or 1000). The shaded area around the lines represents one standard error of the mean. The no migration treatment (dark blue) was used in all future sets of experiments as the baseline.

our intuition (Figure 1): the average donor ability was not statistically different between the treatments at the end of the experiments (two-sample t-test,  $p > 0.2$  for all pairwise comparisons between treatments), and in all but one case, neither was the recipient immunity (two-sample t-test,  $p > 0.05$  except for the comparison between  $mig = 0$  and  $mig = 300$ , where  $p = 0.047$ ). However, the average probability of transfer did generally increase with higher migration (mean value of 0.144, 0.191, 0.243, 0.220 for  $mig = 0, 100, 300, 1000$ , respectively). Overall, in spite of much variation between the replicate experiments, we do find a trend for migration positively affecting the probability of plasmid transfer (all pairwise comparisons are significant, two-sample t-test, with at least  $p < 0.03$ ). Additionally, these differences did not come solely from the change in donor ability or recipient immunity, but the interaction between the two. As transfer happens within a generation and organisms' migration happens between generations in *Aevol*, we cannot account for physical processes that could impede conjugation, such as pili breakage or detachment. Instead, our work suggests transfer is more favored when it can also result in the transferred genes spreading further and faster due to organism migration. These and other selection forces that may increase conjugation in well-mixed populations should be investigated in greater detail.

### Cost of transfer

We continued to quantify the properties of *in silico* transfer by varying the cost of expressing the genes that are involved in moderating the transfer rate. For each transfer-related gene the fitness of a digital individual would decrease proportionally to the product of cost and the increase of the donor ability or recipient immunity. Our expectations were clear: at higher costs of expressing donor genes, less plasmid transfer would evolve. Data supports our hypothesis (Figure 2) and we find

**Figure 2. Effect of cost on donor ability and recipient immunity of plasmid transfer.** Each line is an average value for (a) donor ability and (b) recipient immunity across 20 replicate populations that evolved for 20,000 generations with the same set of parameters. Different colors represent costs of expressing donor ability or recipient immunity genes (0, 0.03, 0.1, or 0.3). The shaded area around the lines represents one standard error of the mean. The data for the baseline populations (dark blue lines, no cost) are the same as the ones used in the Figure 1 (no migration, dark blue line).

**Figure 3. Genetic architecture of transfer.** Four basic population properties, (a) fitness, (b) genome size, (c) donor ability, and (d) recipient immunity are averaged across 20 replicate populations that evolved for 20,000 generations with the same set of parameters. Different colors represent the property values obtained when considering just the chromosome (green), just the plasmid (red), or the entire organism (blue). The shaded area around the lines represents one standard error of the mean. The data for the baseline population (dark blue lines) are the same as the ones used in the baseline runs (no cost, no migration) in the previous figures.

that most transfer evolves when cost was zero ( $p < 0.001$  for comparison with all other treatments), while low levels of transfer evolve at cost 0.03, and effectively no transfer at higher costs. While orders of magnitude less than the rates of transfer in nature, given our relatively small population sizes, the evolved number of transfers per generation is comparable to natural populations. We should note that even when explicit cost of transfer genes was zero, genes that do not increase fitness are quickly lost in *Aevol*, both due to drift and because they may interfere with other genes through large mutations (Knibbe et al. 2007). Given our results and the wide spread of transferable plasmids in nature, we could speculate that their cost of expression may not be greatly different than one incurred by any other genes. Alternatively, such cost could be offset by some direct and strong benefit that plasmids would confer, such as the frequently observed antibiotic resistance (Svara and Rankin 2011).

### Genetic architecture of transfer

We continue the analysis of the baseline runs, with no migration or transfer cost, by examining the location of the metabolic and transfer genes. In nature, the molecular machinery for plasmid conjugation is located on the plasmid itself (Zatyka and Thomas 1998), but individuals could also control plasmid transfer via genes located on the chromosome. We expect that if plasmids confer a cost on their hosts, genes for recipient immunity would be selected for, and located on the main chromosome. In our baseline runs (where individuals evolved without any migration or transfer cost), we observe that the plasmid is the dominant genetic unit of the individual: not only are transfer genes located on the plasmid (Figure 3c, 3d), but it is on average larger than the chromosome (Figure 3b) and carries the majority of metabolic genes (Figure 3a). All the differences are statistically significant, as determined by two-sample t-test, with  $p < 0.01$ . We conclude that plasmids in *Aevol* behave largely like selfish genetic elements, controlling and increasing their own spread, but also taking on other aspects of the organisms' phenotype. Rather than the chromosome being the one who is trying to exclude invading

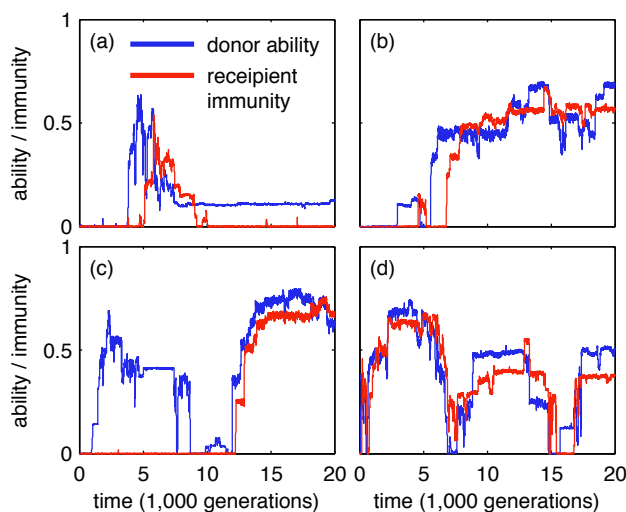

and potentially detrimental plasmids, it is the plasmid that is defending itself from being replaced. However, contrary to intuition of classical plasmid biology, our plasmids evolve to be larger than chromosome and also carry the majority of metabolic genes. Rather than being strictly selfish in their evolution and propagation, they also carry metabolic, directly beneficial genes that may transfer to future hosts. Still, the benefit is at best mutual, since by increasing the host organism's fitness the plasmid also effectively increases its vertical transmission rate and thus the probability of being transmitted into the next generation.

**Figure 4. Examples of the distribution of the fitness genes across genetic units.** We consider four replicate base experiments (no migration, no cost) over 20,000 generations of evolution (a-d). Different colors represent the average fitness measurements obtained when considering just the chromosome (green), just the plasmid (red), or the entire individual (blue).

However, while all experimental populations evolved to comparable fitness levels they have done so by following different trajectories in terms of the gene distribution between the chromosome and the plasmid. In Figure 4, we show some or the possible outcomes from 4 different populations, in which the metabolic genes are solely the plasmid (Figure 4a), on the chromosome (Figure 4b), are shared between the two during most of evolution (Figure 4c) or are constantly jumping between the genetic units (Figure 4d). In multiple panels of the Figure 4 it is obvious that the fitness measured for the plasmid and for the chromosome do not add up to the fitness of the individual. For example, between the generations 1,000 and 4,000 the average fitness of individuals in Figure 4b is much less than what would be expected based on the plasmid and chromosome fitness. Similar antagonistic or synergistic interactions are frequently observed and create an additional channel of interaction between the genetic units. The mechanistic explanation is a straightforward one, with obvious biological parallels. For example, both plasmid and the chromosome may express a gene that confers 0.4 level to a selected trait, raising their fitness when considered alone. However, if the optimal level of the trait is 0.6, the individual with both this chromosome and plasmid will overexpress this gene and may have lower fitness than expected from the contributions of its genetic units. Such interactions between the plasmid and chromosome are also a striking example of the benefits that come from models like *Aevol*, as they could

**Figure 5. Examples of the distribution of the transfer genes across genetic units.** We consider four replicate base experiments (no migration, no cost) over 20,000 generations of evolution (a-d). Different colors represent the average donor ability (blue) and recipient immunity (red) in the population. These examples are representative of the overall pattern of transfer rate evolution in the runs where both donor ability and recipient immunity evolved. Additionally, there were two experiments in which neither donor ability nor recipient immunity evolved (above an *ad hoc* threshold of 0.1 during at least 1,000 generations), as well as three in which donor ability evolved but recipient immunity never did.

not be observed in the classical, analytical models, and even here, they were not something we necessarily expected to see.

### Donor ability and recipient immunity coevolution

In order to examine the dynamics of plasmid transfer evolution, we examine the data from individual experiments, specifically the average plasmid donor ability and recipient immunity over the full course of the experiments. In Figure 5 we show four runs that are representative of the transfer rate evolution in our experiments and note two major trends:

(1) *Recipient immunity evolves only after donor ability.* This can be interpreted as an example of the apparent short-sidedness of evolution. Although immunity to invading plasmids is generally beneficial in the long run, without immediate benefit, any immunity genes are lost to drift.

(2) *A decrease or loss of donor ability is soon followed by the loss of recipient immunity.* As in the previous case, the recipient immunity without donor ability confers no benefit for the organism and is thus quickly lost by drift alone.

We suspect that in situations where recipient immunity is maintained at levels higher than donor ability, such as around generation 7000 in Figure 5a, the genetic architecture constraints relevant genes in a way that makes it difficult to decrease their expression levels without either a decrease in fitness or a complete loss of immunity.

**Figure 6. Evolution of transfer with fixed donor ability or recipient immunity.** (a, c) Comparison of the experiments with freely evolving recipient ability (dark blue line) and ones where the extrinsic recipient immunity was set to zero (green line). (b, d) Comparison of the experiments with freely evolving donor ability (dark blue line) and ones where the extrinsic donor ability was set to a fixed value of 1, 0.3, 0.1 or 0.01. Color legend in panel (a) is relevant for both (a) and (c), and the one in panel (b) for both (b) and (d). The lines are mean values for 20 replicate experiments within each treatment and the shaded area represents one standard error of the mean. The data for evolving donor ability and recipient immunity experiments (dark blue lines) are from the baseline runs, as in the previous figures.

To further assess the co-evolution of donor ability and recipient immunity we conducted two sets of experiments in which one of these traits was not allowed to evolve. When individuals had no possibility to modulate the recipient immunity (Figure 6a and 6c), the donor ability evolved to somewhat elevated, but not significantly higher levels. However, the average probability of transferring the plasmid (calculated just as the difference between the corresponding curves in Figure 6a and 6c) does differ between the two treatments by more than 60% and is significant (two-sided t-test,  $p < 0.001$ ). This indicated there is no optimal level of transfer ability that evolves, at least in the time frame of our study. Instead, the amount of plasmid transfer depends on the environment in which the plasmids are evolving in, and in this case, the ability of individuals to fight off unwanted plasmids.

Finally, we examined the evolution of recipient rate when the individuals cannot evolve their donor ability. In this case, setting the donor ability to zero would not provide any new or interesting outcomes, as all our previous results point to recipient immunity not increasing in the absence of donor ability. Instead, we set the external, unchanging donor ability and let the recipient ability evolve in response (Figure 6b and 6d). We found that recipient immunity does evolve at intermediate levels of base donor ability (0.1, 0.3), but not the extreme ones (1, 0.01). In neither case did the recipient immunity evolve to the levels as high as when donor ability also evolved freely (two-sample t-test,  $p < 0.01$ ). Although the range of constant, pre-set donor ability values was comparable to the ones that evolved freely, the recipient ability just could not compensate and “catch up”. We take this as another strong indication that the evolutionary fate of transfer rate is shaped by the interactions between donor ability and recipient immunity – only when immunity could co-evolve with donor ability, following it at a relatively short distance, it rose to higher values. A closer examination of the order in which mutations arose and spread, across a number of replicate populations, could provide the definite description of this coevolution, but at this time, remains extremely computationally demanding and outside of the scope of this study.

### Plasmid replacement and swapping

Bacterial conjugation is a form of sex, but compared to recombination, it is clearly one-sided and asymmetric: the flow of genetic information is unidirectional as there is a donor and a recipient of the plasmid. Motivated by plasmid retrotransfer, an exception to this rule, we modified the mechanism of conjugation in *Aevol* to swap two plasmids, rather than replace one with the copy of the other during every transfer event. We measured average donor ability (mean =  $1.9 \times 10^{-5}$ , standard error of the mean =  $7.0 \times 10^{-6}$ ) and recipient immunity (mean =  $4.1 \times 10^{-5}$ , standard error of the mean =  $1.7 \times 10^{-6}$ ) in the 20 replicate runs with swapping plasmid. Although both were significantly different than zero statistically ( $p = 0.015$  for donor ability,  $p = 0.027$  for recipient immunity, one-sample t-test) given the extremely low values, we do not consider them to be significant biologically but just a product of mutation-selection balance. We did hope to observe some digital sex, but given our previous results, these outcomes are not surprising. By swapping plasmids, we stopped them from being infectious,

as the frequency of a plasmid could not increase purely via horizontal transfer. Instead, the plasmid transfer-related processes were now closer to sex and recombination and thus subject to similar short-term costs and only long-term benefits. In absence of parasite-driven Red Queen dynamics (Lively et al. 1990), changing environment (Misevic et al. 2010), or one of the other scenarios beneficial for sexual reproduction (West et al. 1999) the organisms are likely to remain asexual, consistent with our results.

## Conclusions

Plasmids represent an important feature of microbial biology, have been extensively studied and used as an important tool in genetics, molecular and synthetic biology. However, many questions remain open, especially relating to plasmid evolution, interactions between the host and the plasmid, genetic architecture, and control over plasmid transfer. Here we presented an implementation of *in silico* transferable elements for the evolution platform *Aevol*. We demonstrate the strength of the approach by tackling classical research question of plasmid cost, but also investigate the evolutionary dynamics of metabolism and transfer genes in a way that would be extremely difficult to do in a natural system. We find signatures of coevolution between donor ability and recipient immunity, which evolve to be primarily, but not exclusively, encoded on the plasmid. Although plasmids seem to behave like selfish genetic elements, they at times also carry metabolic genes and may thus be directly beneficial to future hosts. Finally, during relatively long stretches of evolutionary time, the genes on the chromosome and the plasmid interacted epistatically, highlighting another way these genetic elements may affect each other's evolution. Throughout the study, the general trends were apparent, but were also accompanied by much stochastic variation and great diversity in the evolutionary trajectories. Future studies with *Aevol* will enable close analysis of individual-based effects as well as interactions between plasmid conjugation and other high-impact evolutionary events such as the evolution of cooperation or the evolution of multicellularity.

## Abstract

We aimed to develop a micro-robot that can crawl on contact surfaces in biological environments. The prototype chassis of this micro-bot consists of a lipid membrane that encapsulates and bonds micro-sized magnetic particles. By applying a rotating magnetic field, we hope to obtain a micro-crawler robot. In this report, we describe our observations of the rotational movement of liposomes (10–60  $\mu\text{m}$  in diameter) encapsulating magnetic particles following manipulation of an external magnetic field using a neodymium magnet. Since this robot actively makes contact with the external environment, it will be possible to salvage some important molecule from the contact surface. It is expected that development of this system will lead to the development of new diagnostic and treatment systems.

## Introduction

Since the dawn of history, numerous functional molecules have been discovered and synthesized by scientists. System integration of such molecular devices can facilitate the construction of human-controllable molecular machines. Designing and controlling nano- and micro-meter-sized chemical systems is considered one of the most effective means of examining the invisible small world. Recently, molecular self-organization has been gaining increasing interest with a view to creating higher-order chemical systems at the single-molecule level. This represents a crucial step in the development of the new research field of “Molecular Robotics” [1]. For prototyping a molecular robot, compartmentalization in a homogeneous aqueous solution is an essential requirement. One of the key materials in this regard is a supramolecular structure called the “liposome.” Liposomes consist of a closed phospholipid bilayer membrane and behave as hydrophilic capsules. These lipid vesicles have the property of excellent biocompatibility, are capable of holding various solutions, have readily modified surfaces, and can potentially be prepared in large amounts. Since their discovery, many applications, including carriers of drugs, have been studied.

The liposome “capsule” is essentially floating in a solution. By encapsulating magnetic particles within liposomes, active drug delivery to target tissues could be realized by controlling the external magnetic field. In this regard, studies of the positional control of liposomes in blood vessels using MRI apparatus have been reported [2]. Local accumulation of liposomes in the fluid environment and the control of drug release by applying external stimuli using a high-temperature superconducting bulk magnet have also been performed [3]. However, such floating particles are unable to detect surface

Figure 1: Schematic image of supramolecular micro-crawler.

molecular information. Nevertheless, we have noted that investigations of the interactions between solutions and living surfaces is important for an understand of living systems.

To this end, we have attempted to construct a crawler-type micro-molecular robot (supramolecular micro-crawler; Figure 1). The liposomes of this crawler consist of lipid and adhered-encapsulated magnetic micro-particles. This multicomponent structure is expected to function on tissue in the body environment, for example, via vascular flow, by crawling induced by external rotating magnetic field.

We believe that these types of robots will not only have the ability of remotely controllable drug delivery in three dimensional motion, but will also be able to determine normal or abnormal areas of tissue by sensing the surface molecules through interaction with the cellular-contact surface. We also anticipate the construction of new diagnostic and therapeutic systems, such as the robot described here, and that these will be applied to the treatment of malignant tissue through making a diagnosis of living tissue as a result of rolling on the tissue surface.

In this paper, we present the results of the rotational motion of liposome-encapsulated magnetic beads generated by applying an external magnetic field to construct the micro-robot described above.

## Experiments

We adopted the water-in-oil (W/O) emulsion method to prepare the liposomes (Figure 2) [4]. The composition of the buffer solution used was as follows: 10 mM HEPES-KOH, 2.6 mM  $\text{Mg}(\text{OAc})_2$ , with 20 mM potassium glutamate (pH 7.6). A lipid mixture of 1,2-dioleoyl-sn-glycero-3-phosphoethanolamine-n-(biotinyl) (sodium salt) (biotinyl DOPE), 1,2-dipalmitoyl-sn-glycero-3-phosphocholine

(DPPC), and cholesterol (at molar ratio of 1:1:1) was dissolved in liquid paraffin.

The lipid solution was mixed with the buffer containing 150 mM sucrose, 350 mM glucose and streptavidin magnetic particles (inner solution). This mixture was vortexed for 60 s to form a W/O emulsion. The emulsion was then gently placed on top of the buffer containing 500 mM glucose (outer solution) in a tube. The sample tube was centrifuged and the emulsion was then passed through an oil/water interface

Figure 2: The W/O emulsion method for liposome formation.

saturated with lipids to form a bilayer structure. The procedure is a slightly modified version of that previously described by Nishijima et al. [5].

The top-most W/O emulsion was removed and the liposomes (maximum diameter of approximately 60  $\mu\text{m}$ ) encapsulating magnetic beads were collected by micropipette. The liposomes thus obtained were clearly observable under a phase-contrast microscope (IX-71; Olympus). On the microscope stage, we attempted to observe the rotational movement of liposomes containing the magnetic particles by applying an external magnetic field. The rotational magnetic field was generated using a round-type neodymium magnet ( $\phi$  11 mm  $\times$  3 mm). Sample solution containing liposomes was placed in a hole in a silicone sheet on a slide glass, and covered with a cover glass. The magnet was placed next to the prepared slide on the microscope stage.

## Results and Discussion

The rotating magnetic field was generated in two different ways: (A) by moving the neodymium magnet around the samples, and (B) by rotating the magnet near the samples. The results for each method are shown in Figure 3A and B, respectively. It was possible to perform rotational movement using both methods. The rotational cycle was not fast and limited to  $\sim 0.3$  Hz. Surface resistance between the double-layer of the liposome membrane, and viscosity of the buffer solution should be affected. We then attempted to place the suitable chemical structure onto the liposome surface. The results of this investigation will be discussed in the conference.

In this study, we controlled liposome movement by applying a magnetic field to liposomes encapsulating magnetic particles for the construction of a supramolecular micro-crawler, which will be used to develop new diagnostic and treatment systems, and we succeeded in obtaining rotational motion of the our designed liposomes using two different rotational magnetic fields. We are currently examining the crawling motion of liposomes on surfaces. For this purpose, we will modify the surface properties of the

Figure 3: Rotational behaviors of a liposome using two different methods. Scale bars are 20  $\mu\text{m}$ .

liposomes and the contact surface (e.g., molecular modification and charge), and conduct experiments in static and fluid environments. In addition, we are constructing a device that will be used to rotate the liposomes. We also aim to collect target molecules consisting of fluorescent molecules using a micro-robot prepared from liposomes.

## Abstract

John von Neumann first presented his theory of machine self-reproduction in the late 40's (von Neumann, 1948), in which he described a machine capable of performing the logical steps necessary to accommodate self-reproduction. The proposed architecture was comprised of two distinct components, a passive genotype, which acts exclusively as an information storage of a machine description, and an active phenotype which is responsible for all mechanical functionality of the machine including the ability to decode the genotype and construct the described machine to facilitate self-reproduction. This paper presents an exploratory model which implements the von Neumann architecture for self-reproduction within the pre-existing evolutionary platform of *Tierra*. Initially, the memory image of the automaton's genotype and phenotype are physically identical, and each symbol in memory may be interpreted as either passive numerical data (g-symbol), or a functional instruction (p-symbol), depending on how the symbol is interpreted. If redundancy is introduced to a mutable genotype-phenotype mapping, the mapping system becomes non-invertible, rendering it impossible to compute an automaton's exact genotypic memory image by analysis of the phenotype alone. However, this non-invertible mapping may allow for a more robust genotype, increasing its robustness to fatal mutations and therefore increasing its ability to preserve its phenotypic form under perturbations.

## The von Neumann Architecture for Machine Self-reproduction

Von Neumann's architecture for machine self-reproduction, presented in his theory of self-reproducing automata (von Neumann, 1966; Baugh and McMullin, 2012), describes a machine,  $M$ , which is decomposed into two primary components, a functional component  $P$ , and an passive component  $G$ , such that  $M = (P + G)$  (McMullin, 2012).  $G$  represents a one-dimensional string of symbols which has no active/functional capability, but can be interpreted as information, similar to the *tape* of a Turing machine. The information within  $G$  is used to describe an arbitrary machine  $X$  under some function,  $\phi()$ , such that  $G = \phi(X)$ .

$P$  is further divided into four fundamental subcomponents, a *general constructive automaton*  $A$ , a *general copy-*

*ing automaton*  $B$ , a *control unit*  $C$ , and the *ancillary machinery*,  $D$ .  $G$  will be referred to as the *genotype* while  $P$  will be referred to as the *phenotype*<sup>1</sup>.

The general constructive automaton  $A$  can read the symbols within  $G$ , and interpret them as an encoded description of an arbitrary machine  $X$ .  $A$  has the capability to apply an inverse function,  $\phi^{-1}()$ , or  $\psi()$ , to  $G$ , and construct the described machine  $X$ . We denote this by saying  $\psi(G) = \psi(\phi(X)) = \phi^{-1}(\phi(X)) = X$ . In other words, when supplied with a genotype, the general constructive automaton applies the decoding function  $\psi()$ , to  $G$ , in order to construct the arbitrary machine  $X$ .

The general copying automaton  $B$ , reads and duplicates the machine description  $\phi(X)$ . A control unit  $C$  is required to govern the automaton ( $A + B$ ), directing its operation, activating  $A$  and  $B$  in the correct order, and insuring that the offspring creature is "activated" once its construction is complete.

The forth component, the ancillary machinery  $D$ , refers to all conceivable functionality that the machine may possess which does not interfere or hinder the reproductive operation of ( $A + B + C$ ).

When a machine ( $A + B + C + D$ ) is supplied with a description  $\phi(X)$ , the control unit  $C$  first commands  $B$  to duplicate  $\phi(X)$ . Upon duplication,  $C$  instructs  $A$  to decode  $\phi(X)$  under some inbuilt genotype-phenotype mapping function  $\psi()$ , and construct the described machine  $X$ . Finally  $C$  will attach the new instances of  $\phi(X)$  and  $X$ , and sever them from the parent automaton ( $A + B + C + D$ ), after which there exists the new entity,  $X + \phi(X)$ . Now consider the case where  $X = (A + B + C + D)$ . This system,  $(A + B + C + D) + \phi(A + B + C + D)$  will proceed to construct an offspring automaton and attach it to the description of itself,  $(A + B + C + D) + \phi(A + B + C + D)$ . The parent and offspring are identical, therefore achieving self-reproduction. This machine architecture is demonstrated in Figure 1.

<sup>1</sup>Although von Neumann never used these terms, we now associate the components in question with the genotype and phenotype in organic biology.

Next we consider the case where a random phenotypic perturbation occurs during the construction of  $P$ , affecting  $D$ , so that a machine  $M = (P + G)$  produces  $M' = (P' + G)$ , where  $P' = (A + B + C + D')$ . This machine  $(A + B + C + D') + \phi(A + B + C + D)$  will proceed to decode and copy the unaltered  $G$  under a decoding function  $\psi()$ , to recreate the original machine  $M = (A + B + C + D) + \phi(A + B + C + D)$ , and the phenotypic perturbation is not inherited. For the case where the perturbation affects the description of  $D$  in  $G$ , creating a machine  $M' = (A + B + C + D) + \phi(A + B + C + D')$ ,  $M'$  will proceed to decode and copy  $G'$  under a decoding function  $\psi()$  to create a new machine,  $M'' = (A + B + C + D') + \phi(A + B + C + D')$ , where  $M'' = (P' + G')^2$ .

Should a random perturbation occur when copying the description of  $A$  to an offspring, which results in  $\phi(A' + B + C + D)$ , then the machine  $(A + B + C + D) + \phi(A' + B + C + D)$  will produce  $(A' + B + C + D) + \phi(A' + B + C + D)$ . It is possible that this machine will now have an altered general constructive automaton. Von Neumann/Burks stated “If the change is in  $A$ ,  $B$  or  $C$ , the next generation will be sterile.” (von Neumann, 1966, p. 86), however it is conceivable that a perturbation within the description of  $A$  may only affect the decoding function  $\psi()$  without completely breaking its reproductive functionality.

This machine  $(P' + G')$  may not be sterile, but conduct the altered decoding function  $\psi^*()$  where  $\psi^*(G') = \psi^*(\phi(P')) = (P')^*$ , to construct the machine  $((P')^* + G')$ . If there are changes in the mapping which allow  $(P')^* = P'$ , then the machine  $(P' + G')$  will self-reproduce successfully while conducting a different genotype-phenotype mapping (McMullin, 2000). We aim to scrutinise this intricate detail, and investigate if any additional mutational pathways may emerge as a result of a mutable genotype-phenotype mapping.

## Implementation within the Tierra Platform

Tierra is an artificial life platform where populations of assembler language self-reproducing automatons (creatures) compete with one another within a one-dimensional circular core memory for both CPU time and memory space (Ray, 1991). Each Tierran automaton consists of a CPU with up to six registers, stack memory and an instruction pointer.

Typically, self-reproduction within Tierra is accomplished via *self-copying*, where a creature must inspect its entire memory image in order to construct an identical offspring. This mechanism is loosely analogous to the reproduction process which occurs in the RNA world hypothesis which posits that at the earlier stages of evolution, RNA acted as

<sup>2</sup>It is worth noting that when a perturbation occurs within  $P$ , the perturbation is not inherited in further generations, however when the perturbation occurs within  $G$ , there is a generation delay between when the perturbation occurs in the genotype and when it is expressed in the phenotype.

both template and template-directed polymerase, and there existed no distinction between genotype and phenotype.

In order to implement the von Neumann architecture within the platform of Tierra, the seed automaton must enforce a division of labour between the storage of genetic information and the catalytic functionality, hence recognising the roles of genotype and phenotype.

The phenotype will naturally consist of the three sub-components, a general constructive automaton  $A$ , a general copying automaton  $B$ , and a control unit  $C$ . The control unit segment of the automaton will calculate the offspring size and allocate memory space to construct the offspring. The general constructor segment will incorporate a mutable genotype-phenotype mapping to allow for inheritable variation which may result in new evolutionary trajectories with creatures conducting an altered genotype-phenotype mapping. The general constructor will incrementally read the symbols within the genotype and under some genotype-phenotype mapping, will determine which p-symbols are to be written to the offspring phenotype. Upon construction of the offspring phenotype the copier is activated and the g-symbols within the parent's genotype are incrementally read and written to the offspring genotype. The control unit then activates the offspring automaton, and the reproductive cycle repeats.

## mRNA-Amino Acid Inspired Genotype-phenotype Mapping

In order to encode the phenotype of an automaton, an arbitrary genotype-phenotype mapping must be implemented. The evolutionary trajectory of such an automaton will be in part, determined by the nature of this arbitrarily elected mapping. We can only claim that any phenomenon observed will be specific and characteristic to the specific mapping system which is implemented. For the purpose of this project, a bijective, mono-alphabetic substitution cipher was chosen. This method was loosely based on the genetic code, in which an mRNA, consisting of a one-dimensional string of symbols (nucleotides), is transcribed into a specific string of symbols (amino acids). If a single letter in an mRNA codon gets perturbed, then the affected codon may result in the construction of a different amino acid.

If we implement a similar mapping system which allows perturbations to the genotype which may alter the description of the general constructor, specifically, altering the genotype-phenotype mapping function  $\psi()$ , then we would effectively be implementing a von Neumann reproducer which may give rise to new evolutionary trajectories operating an altered genotype-phenotype mapping.

This type of a mutable genotype-phenotype mapping was facilitated via the inclusion of a lookup table within the general constructor. The lookup table consists of a one-dimensional string representing the full list of p-symbols available within the phenotype space.

Figure 1: A schematic of the von Neumann style architecture of machine self-reproduction. Excerpted from McMullin (2012).

Figure 2: A schematic of a von Neumann style ancestor in Tierra. The genotype-encoding and offspring phenotype construction, and the lookup table comprises the general constructive automaton. The genotype-copying and offspring genotype construction segment comprises the general copying automaton, and the self-inspection and offspring allocation segment comprises the control unit.

During construction of an offspring phenotype, the parent's genotype is incrementally examined by the general constructor. The g-symbol at a memory location is read and interpreted as its underlying binary numerical value. The p-symbol situated at the corresponding relative address in the lookup table is read, and is written to the offspring's phenotype where it will function as an active instruction. The general constructor sequentially executes this process for every location in the genotype in order to decode each g-symbol and construct the offspring phenotype.

In an attempt to replicate conditions early in the phase change from simple RNA replicators to a system of mRNA and amino acids, we implemented an identity mapping from genotype to phenotype, where the content of the one-dimensional memory image of the genotype is physically identical to that of the phenotype. This situation is analogous to that of the RNA world hypothesis, where in order to replicate, an RNA molecule can act as both a functional catalyst, or a string of symbols to be interpreted, depending on whether it is acting as the catalyst or template.

In cryptography we would refer to this identity mapping as being an encryption in which the plaintext is identical to the ciphertext. Plaintext is information a sender wishes to transmit to a receiver and ciphertext is the result of encryption performed on the plaintext using an algorithm, called a cipher. In this case, the phenotype can be thought of as an un-encrypted message which is to be transmitted to the offspring's memory image and the genotype is the ciphertext which was a result of encrypting the phenotype, according to the encoding function  $\phi()$ . The initial decoding function  $\psi()$  is determined by the permutation of symbols within the lookup table. It is worth noting however, that regardless of the initial permutation chosen for the lookup table, the initial description of the lookup table will always remain the same. If we let  $S$  represent the non-permuted list of symbols which exist in the Tierra universe<sup>3</sup>, then the permutation of the lookup table depicts how each individual element within this non-permuted list of symbols is decoded under  $\psi()$ <sup>4</sup>. The lookup table can now be described as  $\psi(S)$ . When we encode a phenotype to acquire the genotype, the encoded lookup table will now be represented by  $\phi(\psi(S)) = \psi^{-1}(\psi(S)) = S$ , therefore, regardless of the initial permutation of the lookup table, the initial description of the lookup table will always take the form of  $S$ .

Our ancestor requires a minimum of 28 phenotypic instructions in order to self-reproduce. The mRNA-amino acid transcription table consists of a genotype space of 64 different codons, but a significantly smaller phenotype space of

<sup>3</sup>In this case, the non-permuted list of symbols is represented by a list of consecutive binary numbers from 000000 to 111111.

<sup>4</sup>The first location in the lookup table represents which p-symbol is mapped onto by 000000. The second position in the lookup table represents which p-symbol is mapped onto by 000001 etc.

Figure 3: The upper figure presents the mapping from mRNA to amino acid. The lower figure presents the initial mapping from g-symbols to p-symbols, implemented with our von Neumann style seed automaton. Red symbols highlight those which are non-employed and grey highlights symbols which initially map onto employed p-symbols.

22 amino acids, plus the start and stop codons. In an attempt to mirror the redundancy of the genetic code, a genotype and phenotype space of 64 was implemented. This corresponds to 64 separate 6-bit binary digits in the genotype space, and 64 phenotypic instructions, 28 of which have an active function and are used within the phenotype and contribute towards self-reproduction, and 36 of which have no active function at all. (See Figure 3.)

## Experimental Procedure

The Tierra soup was inoculated with the described von Neumann style ancestor, (Figure 2).

Point perturbations which affect random memory locations throughout the soup (cosmic rays) and perturbations which occur exclusively to symbols that are being written to memory locations in the soup (copy perturbations) were enabled and the system was run for 100 billion CPU cycles, which is approximately 250 thousand generations<sup>5</sup>. Every strain of creature that emerged throughout the run was captured and the number of employed and non-employed p-symbols within the lookup table for each creature was

<sup>5</sup>A generation in Tierra is a calculated time interval, which is determined by the estimated average amount of CPU cycles required for each creature present in the soup to reproduce once and die.

counted. Employed p-symbols refer to those which have a functional role in the process of reproduction, while non-employed p-symbols are included to introduce redundancy and do not actively contribute towards the reproduction process. If a specific p-symbol exists in the lookup table, then there must exist a specific g-symbol which maps onto it. If a p-symbol is absent from the lookup table then it is lost from the genotype-phenotype mapping. With our current mapping system<sup>6</sup>, it is impossible for a p-symbol which is absent in a parents lookup table to be included in its offspring's phenotype (with the exception of random phenotypic perturbations introducing random p-symbols to an offspring).

The population of employed vs. non-employed p-symbols in the lookup table of each creature was then plotted against the time of emergence of that individual, and this process was repeated 4 times.

## Results

### Standard evolutionary Behaviour

Initial simulations showed evolutionary behaviour similar to that documented in Ray's initial experiments (Ray, 1991). Informational parasitism<sup>7</sup> quickly emerged due to the description of the lookup table being omitted from the genotype. The resulting creature will redirect its CPU to a neighbouring host to facilitate the construction of its phenotype and therefore expend less CPU time per reproduction cycle due to its reduced length. Another evolutionary phenomena typical of Rays experiments is the reduction of creature size by reducing template addresses where possible. Address locations in Tierra are not facilitated via a global address location, but by matching complementary patterns of `nop1`'s and `nop0`'s. While the programmer creating the creature may use an initial template size of four `nop` instructions, evolution will typically reduce the template size where ever possible, creating shorter and more efficient offspring. Other evolutionary behaviours observed when implementing von Neumann style reproduction are the emergence of pathological constructors (Baugh and McMullin, 2012) and the degeneration to self-copiers within in the platform of Avida (Hasegawa and McMullin, 2012).

### Evolution of the Genotype-phenotype mapping

The aforementioned evolutionary behaviours have already been studied and documented, and therefore is not of primary concern, so for the remaining experiments the input parameters were edited so that only offspring of the same length as the initial ancestor are allowed to propagate throughout the memory. This will prevent the distraction of known phenomenon occurring and allow us to fo-

cus on the specific evolutionary lineages which arise as a direct result of a change in the genotype-phenotype mapping. A change in the genotype-phenotype mapping will be most easily recognised by a change in the lookup table.

Initially, non-fatal inheritable silent perturbations<sup>8</sup> of the genotype will occur in the description the lookup table. This will alter the genotype-phenotype mapping and allow previously silent g-symbols<sup>9</sup> to be mapped onto employed p-symbols. This allows single employed p-symbols to be mapped onto by multiple g-symbols.

The initial ancestor has 36 silent g-symbols, which are mapped onto 36 different non-employed p-symbols. As neither the silent g-symbols nor the non-employed p-symbols functionally contribute to the reproduction of offspring, the silent mutations that affect which p-symbol the silent g-symbols are mapped onto are random and arbitrary. However it was found that there was a strong bias towards the mapping of silent g-symbols onto employed p-symbols. During an evolutionary run, we see a sharp decrease in the number of non-employed p-symbols within the lookup tables of newly emerging creatures. Eventually, all 36 non-employed p-symbols are eliminated from the descendants of the initial ancestor, and the 64 positions in their lookup tables will consist almost entirely of employed p-symbols. This result can be seen in Figure 4.

## Discussions

The evolution of the genotype-phenotype mapping will initially be driven predominantly by the underlying physical dynamics of the coding system. The nature of the substitution cypher mapping mechanism employed means that certain perturbations of the lookup table are not directly reversible. This results in a biased drift in the genotype-phenotype mapping, eventually eliminating all non-employed p-symbols from the phenotype by ensuring that they are not mapped onto by any elements of the genotype space.

Figure 5 demonstrates a small section of the lookup table and its description. By studying a creature's lookup table and the lookup table's description, one can deduce the genotype-phenotype mapping that is implemented by that creature. For this small section of the mapping between the g-symbols and p-symbols, we see a set of four g-symbols which are interpreted as 0, 1, 2 and 3, which are mapped onto four p-symbols which are interpreted as `nop0`, `nop1`, `nop2` and `nop3` respectively. The red symbols within the lookup table represent non-employed p-symbols, while the grey symbols within the lookup table's description represent the silent g-symbols which initially map onto a non-employed p-symbol. Figure 5(a) demonstrates the initial 1st

<sup>6</sup>A mono-alphabetic substitution cipher.

<sup>7</sup>Informational parasitism refers to a form of parasitism which accesses and reads a host's memory contents, but does not directly interfere with its functionality.

<sup>8</sup>A silent perturbation is one which alters the genotypic sequence, but does not affect the structure of the phenotype.

<sup>9</sup>By silent g-symbols, we refer to g-symbols which were initially mapped onto non-employed p-symbols.

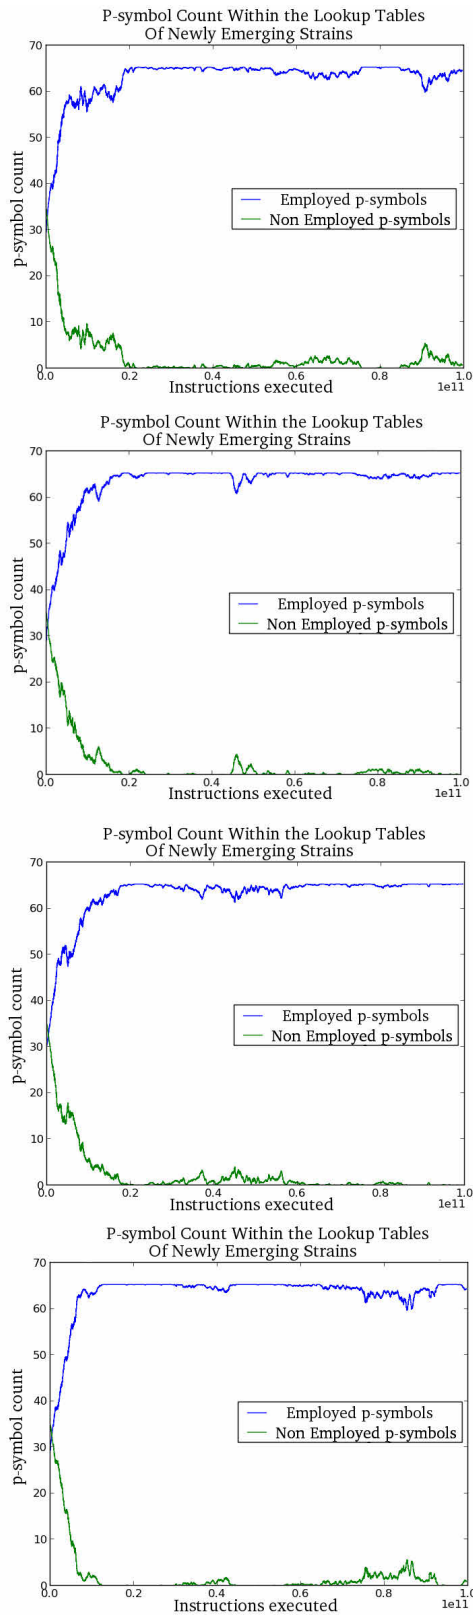

Figure 4: Four evolutionary simulations displaying the number of employed vs. non-employed p-symbols present in the lookup table of strains of newly emerging lineages.

generation ancestor’s lookup table and description. We can see here that the mapping is initially injective and surjective (bijective), as each element of the genotype space is mapped onto a different element of the phenotype space. This mapping is also invertible, as it is possible to determine the exact genotypic sequence by analysis of the phenotype alone. This can be denoted by saying that  $P \triangleq \phi(G)$  and  $G \triangleq \psi(P)$  where  $\psi() = \phi^{-1}()$ .

Figure 5(b) represents an offspring which experienced a perturbation to the third position in the lookup table’s description. For von Neumann reproduction, there is a generation delay between when a perturbation occurs in a genotype and when the perturbation is expressed in the phenotype. When this 2nd generation creature attempts to reproduce, it must first copy its exact genotype to the 3rd generation offspring Figure 5(c). The 2nd generation creature must then decode its own genotype, and construct the 3rd generation creature’s phenotype. However, under construction of the phenotype, when decoding the 2nd position<sup>10</sup> in the lookup table description, the employed p-symbol, `nop0`, is written to the third position in the lookup table, and the previous non-employed p-symbol, `nop2`, is lost from the genotype-phenotype mapping.

Even if the perturbed position in the lookup table description gets perturbed back to the previous state, Figure 5(d), the non-employed p-symbol does not return to the phenotype. This is because the genotype-phenotype mapping has been changed, and now the silent g-symbol, which initially was mapped onto a non-employed p-symbol, `nop2`, is now mapped onto an employed p-symbol, `nop0`.

We also see that the mapping is now non-injective and non-surjective, as an element of the phenotype space, `nop0`, is mapped onto more than one element of the genotype space, 0 and 2. Furthermore, an element of the phenotype space, `nop2`, is not mapped onto by any element of the genotype space. This renders the mapping invertible, as it is now impossible to determine the exact genotypic sequence via inspection of the phenotype alone as  $\psi() \neq \phi^{-1}()$  as now  $G = \psi^*(P)$ .

The only method in which a lost non-employed p-symbol can return to the lookup table is via a genotypic perturbation, which returns the lookup table description to its previous state, followed by a phenotypic perturbation, which directly introduces the lost non-employed p-symbol to the lookup table. Due to this level of ease at which a non-employed p-symbol can be lost, and the level of difficulty required to re-introduce the non-employed p-symbol to the mapping, there is a strong immediate bias present, which quickly eliminates all non-employed p-symbols from the lookup table.

This feature of the implemented mapping system demonstrates how *phenotypic* perturbations are inheritable under the circumstance that the perturbation affects the function

<sup>10</sup>Using zero-based indexing.

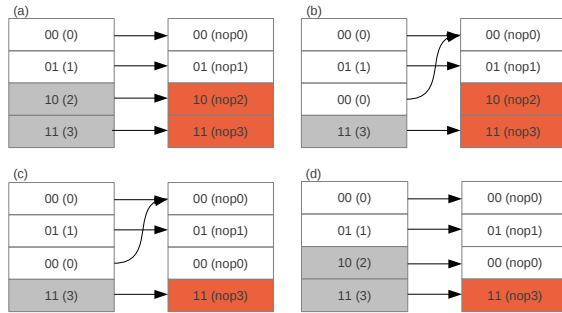

Figure 5: Perturbations to the lookup table description

$\psi()$ . If we have a machine  $X = (A' + B + C + D) + \phi(A + B + C + D)$ , where  $A'$  represents a general constructor with a changed genotype-phenotype mapping  $\psi^*$ , then this perturbation will be inherited to the offspring phenotype only if  $\psi^*(G') = \psi(G')$ , where  $G' = \phi(A' + B + C + D)$ . In other words, this demonstrates an instance of Lamarckian inheritance, where a perturbation of the phenotype is passed down to future generations without any change to the genotype. However, in order for this to occur, the perturbation must affect the component of the phenotype which decodes the genotype, such that the genotype will now be decoded to give rise to the new perturbed phenotype.

**Mutational robustness and Darwinian selection.** Darwinian selection may then sharpen the genotype-phenotype mapping, and create a more mutationally robust genotype. The allocation in which silent g-symbols are mapped upon employed p-symbols may be subject to Darwinian selection. Following a perturbation to a g-symbol, a phenotype may still preserve form if both g-symbols transcribes to the same p-symbol.

If there was no redundancy in the genotype space, then the mapping cannot incorporate inherent mechanism to ensure stability to perturbations and help the phenotype preserve its form under inheritable variation. Every p-symbol will have the same robustness to mutation, no matter how frequently its description occurs in the genotype, or how imperative it is to the correct operation of the phenotype.

For our experiments, we only have 28 employed p-symbols, but 64 g-symbols. Darwinian selection may select how the silent g-symbols are mapped upon the employed p-symbols. A p-symbol which is very common within the phenotype, has a high probability of having its description perturbed within the genotype. If a large percentage of the silent g-symbols are mapped upon the most frequent, employed p-symbols, then the phenotype will have an increased probability of holding form following an inheritable perturbation to the genotype. To test this hypothesis, a creature was

engineered with a non-surjective genotype-phenotype mapping. All silent g-symbols were mapped onto the employed p-symbol, `nop0`. `nop0` is very frequent throughout the phenotype, as it is used for template addressing. The mutational robustness of `nop0`'s description has now greatly increased, as there are 36 possible perturbations which will still allow the phenotype to preserve form. The Tierra soup was inoculated with two von Neumann self-reproducers, the original ancestor with a surjective genotype-phenotype mapping, and the engineered ancestor with the non-surjective genotype-phenotype mapping. The two creatures used different address templates, so that the descendants of each ancestor could be distinguished from each other. This simulation was run for 100 billion instructions and the experiment was repeated 100 times. It was found that in 76 instances the initial ancestor was driven to extinction, while in 24 instances the engineered ancestor with the non-surjective genotype-phenotype mapping was driven to extinction. These preliminary tests show that there may be a selective advantage for distributing the silent g-symbols amongst the most frequently occurring employed p-symbols, and therefore room for Darwinian selection to guide the evolution of the genotype-phenotype mapping. However, this work is pending and requires further experimentation.

The Tierra source code for these experiments along with the analysing software can be found at: [http://alife.rince.ie/evosym/alife\\_2013\\_dbbm.zip](http://alife.rince.ie/evosym/alife_2013_dbbm.zip).

# Indirectly Encoded Sodarace for Artificial Life

Paul Szerlip and Kenneth O. Stanley

Department of EECS, University of Central Florida, Orlando, FL 32826-2363  
pszerlip@eecs.ucf.edu

## Abstract

The aim of this paper is to introduce a lightweight two-dimensional domain for evolving diverse and interesting artificial creatures. The hope is that this domain will fill a need for such an easily-accessible option for researchers who wish to focus more on the evolutionary dynamics of artificial life scenarios than on building simulators and creature encodings. The proposed domain is inspired by Sodarace, a construction set for two-dimensional creatures made of masses and springs. However, unlike the original Sodarace, the *indirectly encoded Sodarace* (IESoR) system introduced in this paper allows evolution to discover a wide range of complex and regular ambulating creature morphologies by encoding them with *compositional pattern producing networks* (CPPNs), which are an established indirect encoding originally introduced for encoding large-scale neural networks. The result, demonstrated through a technique called novelty search with local competition (which are combined through multiobjective search), is that IESoR can discover a wide breadth of interesting and functional creatures, suggesting its potential utility for future experiments in artificial life.

## Introduction

An important aim of artificial life is to uncover the conditions that yield interesting discoveries in evolutionary domains. For example, researchers studying *open-ended evolution* (Channon, 2001a,b; Maley, 1999; Ray, 1992; Standish, 2003; Yeager, 1994) seek to produce dynamics that yield a continual stream of novel and potentially more complex phenotypes. Other approaches to evolving lifelike creatures focus less on the evolutionary dynamics than on a particular property like morphology (Joachimczak and Wrobel, 2012), locomotion (Clune et al., 2011; Lehman and Stanley, 2011a), or both (Auerbach and Bongard, 2012; Bongard and Paul, 2000; Hornby and Pollack, 2002; Krcak, 2007; Lehman and Stanley, 2011b; Sims, 1994). The promise of such investigations is that they can potentially reveal key conditions that lead to the most compelling or natural results.

However, a significant obstacle to entering this research area is the lack of standardized artificial creature domains and genetic encodings. Indeed, in almost all such work

Figure 1: **Sodarace Examples.** Human-designed racers (a) exhibit diverse strategies and morphologies for ambulation while those produced through the evolutionary optimizer (b) share an amoeba-like morphology and similar ambulation.

researchers design their own domains and encodings from scratch, creating a high barrier to entry. In effect there is no out of the box domain that is easy to integrate quickly into a larger experimental framework. For example, an experiment aiming to research the impact of different evolutionary dynamics or selection pressures on open-ended discovery presently requires not only formulating a hypothesis, but also an entire domain and genetic encoding, which may not be the main motivation for the investigation in the first place. While of course sometimes researchers will prefer to build such experiments from the ground up, the availability of an easy, lightweight option that makes it possible to focus quickly on broader evolutionary questions would nevertheless be beneficial to the field overall.

The aim of this paper is to highlight such a lightweight option for a broad creature-space with low barrier to entry. The key concept is to introduce an encoding that opens a *Sodarace-like domain* of two-dimensional ambulatory creatures (McOwan and Burton, 2013, 2005) to broad and diverse evolutionary exploration and discovery. Sodarace is a simulation engine for two-dimensional creatures made of masses, springs, and muscles that ambulate based on the construction of their body morphology. It was originally introduced with human designers in mind, allowing them to construct their own Sodaracers by hand and then race them competitively, yielding a collection of diverse and interest-

ing human-designed morphologies reminiscent of the output of a successful artificial life world (figure 1a). In fact, one version of Sodarace even included an evolutionary optimizer, but because of the simplicity of its genetic encoding, the evolved morphologies only represent a small corner of the possibilities suggested by the human designs (figure 1b).

To open up such a domain to more interesting evolution, a Sodarace-inspired domain and encoding called *indirectly encoded SodaRace* (IESoR) is introduced in this paper that is designed explicitly for evolutionary exploration. In particular, the possibility of evolving a range of natural yet diverse morphologies exhibiting regularities across their structure is created by *compositional pattern producing networks* (CPPNs) (Stanley, 2007) evolved by the HyperNEAT algorithm (Gauci and Stanley, 2010; Stanley et al., 2009). While HyperNEAT and CPPNs were originally introduced to evolve large-scale neural networks, because the creatures in IESoR are also defined fundamentally by nodes and connections, HyperNEAT can in effect also evolve creature bodies with the same regularities and symmetries seen in CPPN-encoded neural networks (Clune et al., 2011).

With this new Sodarace-inspired implementation and an established indirect encoding behind it, the potential for the system to evolve both far more variety and quality than the original Sodarace evolver is demonstrated through a *novelty search with local competition* (Lehman and Stanley, 2011b), which is a recent method for efficiently surveying the range of possibilities that exist within a particular design space. The main outcome is that IESoR indeed introduces a rich and easily accessible platform for exploring a wide variety of interesting creatures with low simulation cost and concrete visual payoff.

## Background

This section contains an overview of Sodarace and MINS, the online projects that serve as the inspiration for IESoR, as well as a brief review of the NEAT and HyperNEAT methods used to encode creature morphology in IESoR.

### Sodarace

The Sodarace project is a simple two-dimensional physics world consisting entirely of masses, springs, and basic oscillatory muscles (McOwan and Burton, 2013, 2005). The goal in Sodarace is to create virtual robots and race them in different environments. Both the robots and the environments are usually hand-crafted by users. However, to aid in creating robots, a construction kit is provided to allow discovery and exploration by the community (McOwan and Burton, 2013, 2005).

The Sodarace project was originally conceived as a type of online Olympics meant to test humans against machine intelligence at the task of designing robot racers. In fact, one redesign of the software includes an evolutionary algorithm that optimizes morphologies for racing. Reflecting the

software's educational aspirations, an online repository of creatures and all relevant software packages are accessible in a centralized location (McOwan and Burton, 2013). At the peak of popularity, Sodaconstructor, the tool for creating the creatures, was played by about a million active users (McOwan and Burton, 2005), suggesting its potential as a platform for exploration and discovery.

### MINS

While Sodarace was a beacon for user creativity, the project itself was created over a decade ago and the community has declined since then. Nevertheless, the peak popularity of the project suggests the domain has wide appeal, though some aspects of the original software make Sodarace inaccessible to academic research. For example, as a closed source Java applet, certain parameters of the races cannot be modified because the Sodaconstructor user interface does not provide user access.

To address the obstacle to research, Stefan Westen created Mins Is Not Sodarace (MINS), an open source replica of the Sodarace environment (Westen, 2013). MINS is fully compatible with Sodarace, allowing the user to import design and environments from Sodaconstructor. By creating an alternative open-source environment, MINS allows adjusting parameters that are hardcoded inside the Sodarace domain. In an effort to curb cheating by Sodarace creatures, MINS alters the environment ceiling size, starting velocities, and maximum movement speeds.

MINS is an inspiration for the work in this paper in part because the variety of creature types found with the Sodaconstructor suggests the space of creatures is rich. MINS also shows that replicating the Sodarace environment is feasible and lightweight, while maintaining backwards compatibility. The primary principle extracted from Sodarace and MINS is the use of masses, springs, and muscles to construct varied creatures inside a customizable physics environment (Westen, 2013).

### NEAT and HyperNEAT

Evolving morphology and control is familiar to artificial life (Auerbach and Bongard, 2012; Bongard and Paul, 2000; Hornby and Pollack, 2002; Krcak, 2007; Lehman and Stanley, 2011b; Sims, 1994). In this spirit, recent additions to Sodarace include a utility with an evolutionary algorithm for creating and optimizing racers inside of the software (McOwan and Burton, 2005). In particular, inside of the Sodarace "Kiosk," users are presented with a limited interface for designing a creature. The user can adjust the number of virtual nodes and muscles along with the amplitude and frequency at which the muscles oscillate. The evolutionary algorithm then searches constrained by those parameters through selection and mutation to find the fastest racer possible. Inside of the Sodarace Kiosk, by default creatures appear to be circular in nature with criss-crossed inner connec-

tions. With gravity, the resulting creatures take on the shape of a semi-circular blob (figure 1b). The Sodarace community refers to this creature morphology as being “amoeba-like.” There is a Sodarace utility called the Amoebamatic that aids users in constructing these amoeba racers.

However, the most interesting handcrafted creatures from Sodarace generally do not exhibit amoeba-like properties. That is, the included genetic encoding is highly constrained to a small subset of all the interesting possibilities. Ideally, the encoding and evolutionary algorithm for evolving such racers would be able to search a wide breadth of possible creatures, which would make this kind of domain relevant to artificial life. Yet to efficiently search such a space requires a principled encoding capable of searching variable levels of complexity.

The first step towards this end in IESoR is the NeuroEvolution of Augmenting Topologies algorithm (NEAT) (Stanley and Miikkulainen, 2002, 2004). Although NEAT was originally introduced as a method for evolving artificial neural networks (ANNs), a major appeal of NEAT is its ability to evolve increasingly complex structures of any type, so that evolutionary search is not limited to a fixed space of possibilities.

Conveniently for IESoR, a method called Hypercube-based NEAT (HyperNEAT) (Gauci and Stanley, 2010; Stanley et al., 2009) builds on NEAT to help it encode large connectivity patterns with natural regularities like symmetry and repetition of structure. While such regularities are useful for neural networks, they can also in principle benefit *bodies* made of connections and joints in a similar way.

The key ingredient behind HyperNEAT is an indirect encoding called a *compositional pattern producing network* (CPPN) (Stanley, 2007). The idea behind CPPNs is that geometric patterns can be encoded by a composition of functions that are chosen to represent common regularities. The internal structure of a CPPN is a weighted network, similar to an ANN, that denotes which functions are composed and in what order, which means that instead of evolving ANNs as it normally does, NEAT can evolve CPPNs that generate a connectivity pattern across a network.

The difference in this paper is that the pattern encoded by CPPNs is interpreted as a body plan for a Sodarace-like creature instead of a neural network. In fact, in a significantly different domain, Auerbach and Bongard (2012) encoded the bodies of three-dimensional ambulating creatures with CPPNs. The indirect CPPN encoding can compactly represent patterns with regularities such as symmetry, repetition, and repetition with variation (Secretan et al., 2011; Stanley, 2007), which are also exhibited by many natural organism morphologies on Earth. In fact, part of the inspiration for CPPNs derives from observations of natural bodies (Stanley, 2007).

To understand how a composition of functions could represent these regularities, simply by including a Gaussian

Figure 2: **Creating a Sodarace-like body using a HyperNEAT CPPN.** In regular HyperNEAT, the CPPN (left) would query the substrate (right) to determine the weights and presence (determined by the LEO output; Verbancsics and Stanley (2011)) of its connections. However, in IESoR the CPPN outputs the muscle, amplitude, and phase parameters for each queried connection instead of a connection weight. That way, the CPPN in effect describes the properties of a Sodarace body instead of a neural network, yet still with the same benefits of HyperNEAT as usual. The resultant creature is placed into a two-dimensional world where it attempts to ambulate.

function, which is symmetric, the output pattern of a CPPN can become symmetric. A periodic function such as sine creates segmentation through repetition. Most importantly, repetition with variation (e.g. such as the fingers of the human hand) is easily discovered by combining regular coordinate frames (e.g. sine and Gaussian) with irregular ones (e.g. the asymmetric x-axis). For example, a function that takes as input the sum of a symmetric function and an asymmetric function outputs a pattern with imperfect symmetry.

In this way, CPPNs produce regular patterns with subtle variations. The potential for CPPNs to represent patterns with motifs reminiscent of patterns in natural organisms has been demonstrated in several studies (Secretan et al., 2011; Stanley, 2007), and suggests such an encoding has potential in the domain of two-dimensional creatures.

Formally, CPPNs in HyperNEAT are functions of geometry (i.e. locations in space) that output connectivity patterns whose nodes are situated in  $n$  dimensions, where  $n$  is the number of dimensions in a Cartesian space. Consider a CPPN that takes four inputs labeled  $x_1$ ,  $y_1$ ,  $x_2$ , and  $y_2$ . This point in four-dimensional space also denotes the connection between the two-dimensional points  $(x_1, y_1)$  and  $(x_2, y_2)$ , and the output of the CPPN for that input thereby represents the weight of that connection (figure 2). By querying ev-

ery possible connection among a pre-chosen set of points in this manner, a CPPN can produce a connectivity pattern, wherein each queried point is a node position. Because the connections are produced by a function of their endpoints, the final structure is produced with knowledge of its geometry. In effect, the CPPN paints a pattern on the inside of a four-dimensional hypercube that is interpreted as the isomorphic connectivity pattern, which is the origin of the name hypercube-based NEAT (HyperNEAT). Connectivity patterns produced by a CPPN in this way are called substrates so that they can be verbally distinguished from the CPPN itself, which has its own topology. While the substrate in the original HyperNEAT is interpreted as an ANN, in IESoR the substrate is a creature's body, as explained next.

## Approach

This section describes the implementation details of IESoR, and explains the variant of HyperNEAT that enables it to create and evolve body plans.

### IESoR

IESoR implements three primary properties derived from Sodarace and MINS (figure 2):

1. The environment is two-dimensional and creatures consist solely of masses, springs, physical joints, and muscles.
2. In creature bodies, masses are implemented by nodes and springs are connections attached at the joints.
3. Muscles manipulate the length of connections, leading to motion.

In contrast to more complicated three-dimensional domains (Auerbach and Bongard, 2012; Krcah, 2007; Lehman and Stanley, 2011b; Sims, 1994), to support robust alife evolution IESoR is designed to be simple to modify and inexpensive to simulate. In the spirit of accessibility and extensibility of the Sodarace project, IESoR implements a Sodarace-like simulator in javascript built on top of Box2D (box2d.org), an open-source two-dimensional rigid body physics engine. There is a small performance hit for programming in a scripting language, but javascript allows the domain to be accessible through the browser for most modern computing devices, from phones to tablets to more traditional PCs. In addition, Box2D physics enables rich environments for testing creature morphologies. Finally, Box2D has been ported to most popular programming languages, which means IESoR could be ported without significant effort.

### Encoding Morphologies with HyperNEAT

Bodies inside of IESoR consist of masses with variable or fixed length constraints. Each constraint, or connection, is represented by a distance joint in Box2D (i.e. a constraint on the length between two masses) and has three distinct properties:

1. The joint is either variable or fixed length (i.e. a muscle or a bone).
2. The change in distance during muscle contraction is the muscle amplitude.
3. The phase shift of the sinusoidal function controlling muscle length is the muscle phase.

Fixed length connections, or bones, do not receive a magnitude or phase from the CPPN.

Recall that HyperNEAT paints a four-dimensional pattern across the weights of a network by querying a CPPN for every pair of nodes in the substrate. The insight in this paper is to take this concept of a substrate and extend it to two-dimensional morphologies. Instead of painting a pattern of weights across the substrate, the CPPN encodes both what joint constraints should exist between masses on a two-dimensional plane and their three virtual properties (i.e. bone or muscle, amplitude, and phase). For this purpose, the CPPN requires four outputs (as shown in figure 2).

Before clarifying how a HyperNEAT substrate can be used to represent a morphology, it is important to consider the placement of bones and muscles in natural body plans. The skeletal system is crucial to mobility at a fundamental level. Equally important to where bones are placed in a body plan is the concept of where bones *are not* placed. If a rough representation of the human body was drawn on a small grid of dots, the principle of symmetry is as important as the fact that there is no bone connecting the tip of the foot to the top of the skull. Morphologies generated in IESoR ideally also should usually respect this simple principle of locality.

Conveniently for this purpose, HyperNEAT can be expanded with a special Link Expression Output (LEO) (Verbancsics and Stanley, 2011) to generate an *expression pattern* that controls whether connections are expressed at different locations independently of other CPPN outputs. In Verbancsics and Stanley (2011), HyperNEAT with LEO was seeded with a bias towards favoring locality although evolution could adjust this bias during search.

To generate a morphology using an  $n$ -by- $n$  grid of nodes as the substrate, for each node location in the substrate (figure 2), the CPPN queries all other node positions. The  $(x, y)$  coordinate of nodes  $i$  and  $j$  are denoted as  $(x_i, y_i)$  and  $(x_j, y_j)$ , respectively. The input into the CPPN is thus  $x_i, y_i, x_j, y_j$ , and there are four outputs. First, the LEO output (which is a step function) is checked for a positive value. If LEO is positive, a connection is placed between nodes  $i$  and  $j$  from  $(x_i, y_i)$  to  $(x_j, y_j)$ . Then the output that determines whether the connection is a bone or a muscle is queried. If the output value is below a pre-defined *muscle threshold*, the connection becomes a fixed-length constraint. Otherwise, the constraint is a muscle, and the amplitude and phase of the muscle contraction are read from the remaining two CPPN outputs. Finally, to further reduce complexity in the resultant morphologies and keep computational costs

low, pairs of points greater than a third of the diagonal length of the substrate are not queried while constructing the two-dimensional creatures. An example of a fully constructed morphology is shown in the lower right of figure 2.

After assembling the masses and joints, the bodies are placed in a simple Box2D environment consisting of the ground, gravity, and friction. As the world is simulated, muscles oscillate according to the amplitude and phase values defined by the CPPN, while bones remain a fixed length. Creatures occupy distinct Box2D environments, and nodes cannot collide with each other.

## Experiment

Though its creatures are mainly hand-crafted, Sodarace shows that the space of possible two-dimensional body types is likely filled with creatures capable of movement. As noted in Section 2.3, the Sodarace Kiosk went on to create an automated approach to generating creatures, but resulted in a highly restricted space of bodies. The experiment described in this section is designed to show that not only is an automated approach capable of designing two-dimensional walkers, but the method can also produce a *wide variety* of different means for locomotion, thereby giving hope for further application of Sodarace-like creatures in artificial life.

### Novelty Search and Local Competition

To best demonstrate the morphological diversity possible in IESoR, Pareto multiobjective search (based on NSGA II) (Deb et al., 2002) including both novelty and local competition (Lehman and Stanley, 2011b) is implemented to explore the space of body types. Lehman and Stanley (2011b) first applied Pareto multi-objective search with novelty and local competition to yield a diverse group of ambulating three-dimensional morphologies all within a *single run* of evolution. Maintaining and exploiting diversity across evolution is both an impressive and important part of validating the potential for future artificial life research with IESoR.

The first of the three objectives that make up novelty search plus local competition is novelty search, which was introduced by Lehman and Stanley (2008, 2011a) to avoid the common pitfall of evolution prematurely converging on a deceptive objective. Novelty search aligns well with the aim of this experiment because the hope is to find a diversity of novel creatures. Joachimczak and Wrobel (2012) have shown before that novelty search can be effective for this purpose. The characterization of creature novelty for the novelty search component can significantly impact evolution and strongly bias the resulting creatures discovered. In this experiment, novelty search characterizes creatures by their width, height, and mass (as measured by the number of nodes and the sum of the connection lengths) at the first time-step of the simulation, which should lead to a visually diverse population. The novelty metric is the squared Euclidean distance separating two individuals in this charac-

terization space, and thus the novelty of a creature is proportional to how different its starting morphology is from that of other creatures currently in the population. Such a characterization space especially encourages creatures with varying widths, heights, and masses.

The second objective, local competition to walk farthest, forces individuals to compete *only* with those who are characterized as similar (Lehman and Stanley, 2011b). The idea is that within novelty search it is possible to push individuals who are similar with respect to the behavior characterization to compete locally to be the best of their type. That way, globally novelty search probes a wide variety of possibilities, but locally individuals optimize to be the best they can. In IESoR, creatures who are locally close share similar widths, heights, and masses, ideally indicating a similar morphology. Local competition is the mechanism for pressuring individuals with related morphologies towards more effective locomotion.

As in Lehman and Stanley (2011b), the Pareto multi-objective search has three objectives: novelty, local fitness, and finally *genotypic diversity*. The genotypic diversity objective encourages exploring innovative genotypes by assigning higher values to more novel genotypes. That way, new genotypes created by HyperNEAT are not initially penalized and thereby have a chance to optimize to reach their potential. This genetic diversity objective is in effect a multiobjective-compatible substitute for the usual speciation mechanism in NEAT, which serves the same purpose. Additionally, the genotypic diversity objective is also localized within the characterization space; similar in motivation to that of local competition, local genetic diversity ensures that genotypic diversity is not only exploited in those characterization niches in which such diversity is incidentally most easily expressed.

In all setups, the distribution of individuals in behavioral space as well as their overall performance is recorded. The idea is to quantify how much morphological diversity is discovered and maintained and how well each behavioral niche is being exploited overall throughout a run.

### Experimental Parameters

The overarching multiobjective algorithm is based on NSGA II (Deb et al., 2002). The population size is 120, and a run consists of 1,200 generations, resulting in 144,000 total genomes evaluated. The nearest-neighbor size for novelty search and local competition is 20. The three morphology dimensions used to characterize novelty (i.e. width, height, and mass) are rescaled so that their values fill the range between zero and three. The selection method for NSGA II was tournament selection (with tournament size two), and other parameters followed precedent Lehman and Stanley (2011b), which in turn used the parameters of Krcak (2007).

## Results

The intention of the experiment is to demonstrate that a wide variety of walkers exists in the encoding space defined by IESoR, thereby establishing the viability of IESoR for future alife research. Thus, as opposed to machine learning experiments aimed at demonstrating optimality, the aim in this experiment is to show both diversity and competence. Recall also that novelty search plus local competition is designed to return a significant coverage of possible solutions from a single long run. There is precedent for demonstrating the diversity that results from such a search. For example, Lehman and Stanley (2011b) measured the height and mass of three-dimensional morphologies from novelty search plus local competition to show the breadth of morphologies discovered by evolution, while Joachimczak and Wrobel (2012) used principal component analysis (PCA) to demonstrate coverage across morphological space after novelty search. Following this precedent, to quantify IESoR's ability to create diverse walkers, PCA is run across characterizations all 144,000 creatures from 1,200 generations of evolution to create a visualization of the resultant diversity.

In particular, to characterize morphological diversity in IESoR for the purpose of visualization, three dimensions that describe gross creature characteristics (i.e. width, height, and mass) are projected into a two-dimensional space by the PCA algorithm. However, while PCA with this information can reveal the diversity across the morphological space, the goal of this analysis is also to give a sense of the competence of such creatures as well. That way it becomes possible to observe the *diversity of competent creatures* instead of just diversity overall. Therefore, in the visualization of the PCA output in figure 3, to ensure the graph shows the diversity of only competent walkers, only points for walkers that ambulate beyond 200 units (which is several times a creature's maximum body length) are displayed. Furthermore, the size of each point's radius is proportional to the absolute distance traveled by the creature beyond 200 units.

Because thousands of points result, the visualization is further refined to reduce clutter and ensure that each point represents a genuinely unique individual. For this purpose, the plane is discretized into  $40 \times 40$  equally sized "bins." Creatures are placed into bins according to the coordinate assigned by the PCA process. Conceptually, each bin thus represents a similar area in morphological space, and the creature assigned to a bin that traveled the farthest among all in that bin is chosen as the representative of that bin. That way, the circles in figure 3 show the best performance for the morphological class represented by its respective bin, and each circle represents a distinct morphological class. Any bin without a representative (shown as empty space in figure 3 lacks an individual who could ambulate at least 200 units.

Of the 1,600 possible bins, 450 are filled with individuals who can ambulate the minimum distance, covering in total 28.1% of all possible bins. Furthermore, the visualization

in figure 3 exhibits the breadth of coverage of competent morphologies. In effect, IESoR with novelty search plus local competition uncovered hundreds of unique and effective ambulation methods covering a significant breadth of conceivable strategies.

Equally important as this quantitative perspective is a qualitative analysis of the breadth of behaviors. It is important to note that every behavior in figure 3 can be viewed at <http://eplex.cs.ucf.edu/ecal13/demo/PCA.html> through a special online interface where the user can click on any point and see the corresponding creature behavior. This fast interactive visualization of hundreds of creatures is possible in part due to the lightweight, inexpensive nature of Sodarace-like creatures, which is one of their potential advantages for researchers in artificial life. Figure 3 also shows a sampling of morphologies, while figure 4 shows a subset of those at different stages of ambulation.

An additional important further qualitative observation is the significantly broader diversity seen in IESoR compared to the original Sodarace evolver's amoeba-like creatures shown in figure 1b. Among those that can be observed are gaits based on loping (degrading into pushing) (figures 3a/4a), pogo-stick hopping (3b/4b), multiple cascading octopus legs (3c/4c), dragging (3d/4d), complex galloping (3e), sliding and pumping (3f), and bouncing into a long dive (3g). Some strategies depend on an initial burst of propulsion, while others rely on stable and consistent ambulation. Some of the very best gaits (largest circles in figure 3) involve galloping or hopping, though even among the very best the diversity of approaches is significant.

## Discussion

The most important implication of the results is that Sodarace-like domains do contain a diversity of viable walkers that can be systematically discovered with the right encoding and selective pressures. Unlike with the early evolver application built for Sodarace, morphologies evolved in IESoR do not exhibit only a single stereotypical organizational motif. Instead, they ambulate in many different ways, from legged-style locomotion to serpentine pulsation to periodic lunges, suggesting the potential for more elaborate applications of this kind of technology in the future.

For example, because the IESoR creatures are inexpensive to simulate, they are amenable to web-based interaction. In fact, the demonstration at the website actually simulates evolved discoveries in real-time through javascript, obviating the need even for video. This ease of simulation means that IESoR creatures can smoothly integrate into interactive evolutionary applications, artificial life worlds, or even interactive simulations allowing human intervention. Additionally, the framework can potentially be extended to three dimensional creatures using current browser technologies.

Investigations relevant to artificial life on open-ended evolution (Channon, 2001b; Maley, 1999; Ray, 1992;

**Figure 3: PCA-based Visualization of Morphological Diversity and Performance.** The location of each point represents its respective creature morphology, while the size indicates the absolute fitness. All points shown are for creatures able to walk at least 200 units. A total of 28.1% of all 1,600 possible bins are filled with competent walkers, suggesting the diversity of ambulation methods. Furthermore, several creatures are shown to give a sense of qualitative diversity. The creatures for every point in this visualization can also be viewed in motion at <http://eplex.cs.ucf.edu/ecal13/demo/PCA.html>.

Standish, 2003; Yaeger, 1994) and diversity maintenance (Lehman and Stanley, 2011b; Mouret and Doncieux, 2012) can thus be quickly set up and conducted in the future with IESoR. Creatures can also potentially move beyond forward ambulation to more complex interactions such as foraging or predation. To facilitate such future applications, code for IESoR is available at <https://github.com/OptimusLime/IESoR>.

## Conclusion

The paper demonstrated IESoR, a lightweight two-dimensional platform for evolving ambulating creatures inspired by Sodarace (McOwan and Burton, 2013, 2005). The aim is to provide an accessible platform to artificial life researchers that is inexpensive to simulate. That way, artificial life experiments that previously required significant up-front design can become easier to ramp up and build quickly. Results from searching through the indirectly-encoded creature space in IESoR with novelty search plus local competition suggest that the space indeed contains a breadth of feasible morphological discoveries with functional ambulatory capabilities, suggesting that IESoR is potentially a viable platform for artificial life research in the future.

## Abstract

In the past decade, thanks to abundant data and adequate software tools, complex networks have been thoroughly investigated in many disciplines. Most of this work has dealt with networks in which distances do not have physical meaning and are just dimensionless quantities measured in terms of edge hops. However, in many cases the physical space in which networks are embedded and the actual distances between nodes are important, such as in geographical and transportation networks. The Random Geometric Graph (RGG) is a standard spatial network model that plays a role for spatial networks similar to the one played by the Erdős–Rényi random graph for relational ones. In this work we present an extension of the RGG construction to define a new model to build bi-dimensional spatial networks based on energy as realistic constraint to create the links. The constructed networks have several properties in common with those of actual social networks.

## Introduction

Social networks arise in a wide range of contexts and are really pervasive in our society. Examples range from corporate partnership connections, scientific collaborations, sexual contacts, film actors networks, to Facebook and other online social networks among others. In recent years much attention has been given to model these networks in order to gain a better understanding of their general structures and their functions like information flow, locating individuals, disease spread, etc. There is an increase in the number of network models in the literature (Toivonen et al., 2009) but, although general features common to all social networks are reproduced, such as the typically high clustering, none of them can represent all the typical characteristics of social networks in a realistic way. This is due to the fact that all these networks have formed and grow in ways that are similar but not identical. In other words, each actual network is an instance of a class of possible realizations and its particular structure depends on its particular history, frozen structures, dynamics, and many other factors.

It is generally believed that social networks possess the following main features:

- *positively skewed degree distribution*: the majority of agents have relatively small degrees, while a small number of agents may have large degrees.
- *high average clustering coefficient  $\bar{C}$* : the conditional probability that two neighbors of an agent will be connected is much higher than what would be expected in a sparse random graph.
- *positive degree correlations*: the degrees of the neighbors are not independent and are similar on average.
- *small average shortest path length  $\bar{L}$* :  $\bar{L} \propto \log(N)$  i.e. it is rather small compared to the network size  $N$ .
- *existence of community structure*: clusters of agents which are highly connected within themselves but loosely connected to other subgroups.

In the last decade social networks as a topology-free relational graph structure have been much studied. A comprehensive literature would be too long to mention, but review articles and books contain a wealth of information on them e.g. (Boccaletti et al., 2006; Newman, 2010). Relational networks are those in which actual distances do not count and path lengths are computed by simply adding one for each link in the path. Social networks such as coauthorship networks are usually taken to be relational. However, Euclidean space is an important factor in many networks, for example transportation and communication networks among others are of this kind (see (Barthélemy, 2011) for a recent good review of the field). But spatial aspects can also be important for social networks. For example, while two Facebook friends might live in the US and Europe respectively and still be represented by a standard link in the net, it is also observed that many links will be among people that are geographically close. Thus, spatial considerations may play a role in social networks too. Therefore, while purely relational social network models are important and have been studied in depth (see e.g. Toivonen et al. (2006); Vázquez (2003); Kumpula et al. (2007); Catanzaro et al. (2004)), their spatial aspects are much less known (but see the following

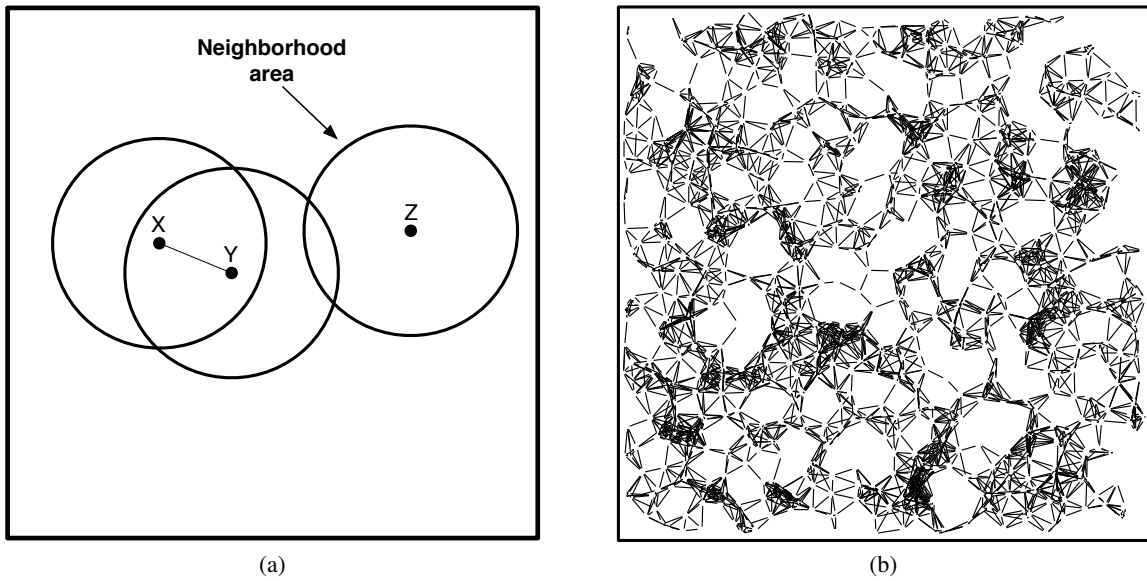

Figure 1: (a): Neighborhood areas of nodes  $X$ ,  $Y$  and  $Z$ . (b): An example of RGG with  $N = 1000$  and  $R = 0.056$ , and average degree  $\bar{k} = 10$  (for illustrative purposes the unit square is bounded).

works Boguñá et al. (2004), Wong et al. (2006) and Serrano et al. (2008) for some recent attempts). Our model is very simple and it is intended to be only a first step toward more realistic ones. It is based on the concept that each agent is initially given a constant amount of energy to be used to establish links with other agents. The spatial bias is given by the fact that links cost less if they are made with agents that are physically closer. The model gives rise to networks that have high clustering coefficient, positive degree assortativity, and modularity due to the appearance of communities. The degree distribution is rather peaked but the model could be easily modified to produce broader distributions.

The article has the following organization. In the next section we give a brief introduction to random geometric graphs, a spatial model that will be needed in the sequel. Next we describe our own model of a social spatial network. The following section presents and discusses the main numerical results, and we then give our conclusions.

### Random Geometric Graph

The Random Geometric Graph (RGG) is obtained when the points located in the plane are connected according to a given geometric rule. The simplest rule is a proximity rule which states that nodes only within a certain distance are connected. There is an extensive mathematical literature on geometric graph and the random case was studied by physicists in the context of continuum percolation (Penrose, 2003; Dall and Christensen, 2002; Barthélemy, 2011).

In this work we refer to the following construction process for a RGG with  $N$  nodes and radius  $R$ :

- the  $N$  nodes are placed on the unit space  $\Omega \in \mathbb{R}^2$  with

uniform distribution,

- an edge is created for every pair of nodes whose distance is  $r < R$ . The distance is given by the standard Euclidean metric on  $\mathbb{R}^2$ .

Furthermore, we shall assume that the unit space  $\Omega$  is the square  $[0, 1]^2$  with cyclic boundary conditions (torus). In Fig. 1a three nodes  $X$ ,  $Y$ ,  $Z$  and their neighborhood areas are depicted. Nodes  $X$  and  $Y$  are connected through an edge since they are within the neighborhood area of each other respectively, while  $Z$  is not connected to  $Y$  even if it is sharing a common area with it. Figure 1b shows a RGG realization with  $N = 1000$  and  $R = 0.056$ ; in this case, for illustrative purposes,  $\Omega$  is a bounded unit square.

It is also possible to adopt different shapes of neighborhood area generated according to other metrics. For example, the Manhattan distance is sometimes used to model mobility networks (Glauche et al., 2003; Di Crescenzo et al., 2012). The general properties of these networks are very close to those using the more common Euclidean distance, which are the ones we describe here.

The average degree  $\bar{k}$  of a RGG can be easily estimated by the formula  $\bar{k} = \rho V$ , where  $\rho$  is the node density, representing the number of nodes within a unit space, and  $V$  is the neighborhood area. In this case  $\rho = N$ , since  $\Omega$  is an unit space, and  $V = \pi R^2$ . In conclusion,  $\bar{k} = \pi N R^2$ .

The degree distribution of RGGs with a sufficiently large number of nodes can be estimated by the Poisson distribution with parameter  $\lambda = \bar{k}$  (Dall and Christensen, 2002).

The average clustering coefficient is given averaging on all node's individual clustering coefficients (Newman,

2010). This property on RGGs was extensively studied in the work of Dall and Christensen (2002), in which they have found the law for the average clustering coefficient as a function of the dimension of the space. Here the dimension is equal to two, and it is possible to demonstrate that the average clustering coefficient tends to  $1 - \frac{3\sqrt{3}}{4\pi} \sim 0.5865$ , for large values of  $N$  and for all 2-dimensional RGGs in the Euclidean space. This important result depends on the particular construction of RGGs. The average clustering coefficient tends to the ratio of the average shared neighborhood area of two connected nodes and the whole neighborhood area. It is clear that changing the radius  $R$  this fraction maintains the same value.

Due to its construction process, in a RGG there is positive degree-degree correlation. This property is commonly detected studying the *assortativity coefficient*, which is the Pearson correlation coefficient of degree between pairs of connected nodes (Boccaletti et al., 2006). In the recent work of Antonioni and Tomassini (2012), it has been demonstrated that the assortativity coefficient tends to the average clustering coefficient value for any  $d$ -dimensional RGG. Many other properties of RGGs have been studied in Penrose (2003).

### Energetic Spatial Network

In order to construct more realistic social networks with spatial structure, we now consider the following two realistic assumptions for a spatial social network (see Fig. 2):

- *limited neighborhood*: a given node may create links only within the set of nodes in its neighborhood area given by the radius  $R$ .
- *distance cost*: creating a long link is more costly in terms of energy expenditure than creating one closer to the focal node.

Figure 2: Node  $X$  can be linked only to nodes within its neighborhood area given by radius  $R$ . In this case, creating a link with  $Y$  is more costly than creating one with  $Z$ .

In this model we assume that *energy*, which is constant and the same for each node, is a resource provided to nodes in order to create and maintain their links. We shall call networks constructed according to this model as Energetic Spatial Networks (ESNs). Our hypothesis is thus that each node has limited energy available to create its acquaintances, which are increasingly costly with increasing physical distance. This feature can be also assumed in actual social networks, in which real distance may play an important role in order to establish a connection. It is indeed reasonable to think that in order to minimize the efforts and to maintain a social tie most individuals tend to be connected with their spatial neighbors, at least in social networks that are not fully mediated by communication devices. The present model creates a static network; dynamical aspects might be included in the future by requiring that maintaining links through time also costs a certain amount of energy.

The construction process to build ESNs with  $N$  nodes, radius  $R$ , and initial energy  $E$ , can be summarized as follows:

1. The  $N$  nodes are randomly placed with uniform distribution on the unit space  $\Omega \in \mathbb{R}^2$ . All nodes have the same initial energy equal to  $E$ .
2. A node  $X$  is picked uniformly at random in the set of all nodes, and  $Y$  is chosen uniformly at random in the set of nodes whose distance from  $X$  is  $r < R$ .
3. An edge between  $X$  and  $Y$  is created if  $d_{XY}$ , which is the Euclidean distance between  $X$  and  $Y$ , is less than  $E_X$  (residual energy of  $X$ ) and  $E_Y$ . If the edge is created, then the residual energies of  $X$  and  $Y$  are both decremented by  $d_{XY}$ .
4. Steps 2–3 are repeated until no more edges can be created according to the linking rule.

The unit space  $\Omega$  can be seen, similarly to the RGGs construction, as the square  $[0, 1]^2$  with cyclic boundary conditions (torus). It is rather clear that this construction process produces RGGs for  $E \rightarrow \infty$ , while, for  $\{R, E\} \rightarrow \infty$  complete graphs are obtained.

### Results

Figure 3 shows empirical values of the normalized average degree, average clustering coefficient, and assortativity coefficient of a realization of an ESN as a function of the initial energy  $E$  (Fig. 3a), and of the radius  $R$  (Fig. 3b). The normalized average degree  $k_{norm}$  shown in Figs. 3 is obtained by dividing the average degree  $\bar{k}$  of an ESN by the average degree of a RGG with the same radius  $R$ . This means that for  $\bar{k}_{norm} \rightarrow 1$  the ESN can be approximated by a RGG. In Fig. 3a, the parameters of an ESN are  $N = 10000$  and  $R = 0.04$ . We can observe that for high values of the initial energy  $E$  ( $> 1.5$ ), ESN features become closer to those of a

Figure 3: Numerical values of normalized average degree, average clustering coefficient, and assortativity coefficient of an ESN as a function of : (a) the initial energy  $E$  and (b) the radius  $R$ . (a): The other ESN parameters are  $N = 10000$  and  $R = 0.04$ . The average degree is normalized dividing by 50, which represents the average degree value of a RGG with parameters  $N = 10000$  and  $R = 0.04$ . (b): The other ESN parameters are  $N = 10000$  and  $E = 1.0$ . The average degree value is normalized dividing by  $10000\pi R^2$ , which represents the average degree of a RGG with  $N = 10000$ .

Figure 4: Degree distribution functions for ESNs with  $N = 10000$  and  $E = 1.0$ . The other parameter, the radius  $R$ , assumes the following values: 0.02, 0.04, 0.06 and 0.1.

RGG since in this case the energy is more than enough to allow the creation of all possible links within radius  $R$ . In fact, average clustering and assortativity coefficients both tend to the characteristic RGG value 0.5865. Therefore, with this model, it is possible to select a value for  $E$  that will produce a desired high clustering coefficient for the ESN. This is not possible with the standard RGG model, which converges by construction to a fixed value.

In Fig. 3b, the parameters of the ESN are  $N = 10000$  and  $E = 1$ . For small values of  $R$  ( $< 0.04$ ), ESNs can be considered as RGGs, because the radius is rather small compared to the initial energy and the nodes can build all the possible links in their neighborhood areas. For larger values of  $R$  the network becomes more interesting. The clustering coefficient and the assortativity coefficient both decrease and thus suitable values of  $R$  for a social network are around 0.04 – 0.06. The normalized average degree is approximately 1 for  $R < 0.04$ , but then tends to zero for larger values of  $R$ . This means that ESNs become sparser than a RGG with the same radius  $R$  and thus  $R$  should not go beyond 0.06 for a realistically connected network.

For  $E = 1$ , Figure 4 depicts the degree distribution functions of four realizations of ESNs with different values of  $R$ . The thick curve with  $R = 0.02$  gives rise to a standard RGG as we have seen above (see also Fig. 3b). The other curves correspond to three ESNs and are rather peaked. Although relational social networks usually have rather broad

Figure 5: Realization of an ESN with  $N = 1000$ ,  $E = 0.64$ , and  $R = 0.1$ . The average degree is about  $\bar{k} = 10$ , while the average clustering coefficient is equal to 0.205 and the assortativity coefficient is 0.135. The modularity is  $M = 0.758$  (Blondel et al., 2008). (a) Spatial representation, and (b) graphical representation given by the OpenOrd algorithm (Martin et al., 2011).

degree distribution functions (Newman, 2001a,b; Barabási et al., 2002; Tomassini and Luthi, 2007), spatial constraints do not allow agents to have too many links to other nodes. The effect is particularly evident in technological and transportation networks where hard constraints such as rail crossing or economic factors in cable length in power grids, for instance, set well defined limits to the network's connectivity (see Barthélemy (2011) and references therein). The above factors arising from spatial physical constraints are less important for social acquaintances but, to some extent, they also influence the spatial structure of social networks. Indeed, social networks can actually be seen as a mix of relational and spatial factors. However, part of the observed effect on the degree distribution function is certainly attributable to the fact that we give the same constant amount of initial energy to all nodes. A simple improvement of the model would consist in attributing energy according to a more complex distribution such as a power-law or another suitable function.

The presence of communities, which are clusters of densely connected nodes, is a common feature of all social networks (Newman, 2010). Communities may arise in many ways, for instance people having common interests, people sharing the same culture or religion, going to the same school, living in the same area, as is the case in our model networks, and many others. We have studied the cluster structure of ESNs using one of the several heuristic community detection algorithms (Blondel et al., 2008)

and we have found that ESNs present several communities. Figure 5 shows an ESN with  $N = 1000$ ,  $E = 0.64$ , and  $R = 0.1$ . Figure 5a is a true geographical representation of the network and, although it might superficially look very similar to the RGG image of Fig. 1b, it possesses features such as the presence of longer links and the lack of linking to all the neighbors falling into the disk-shaped neighborhood area for a given node. Instead, Fig. 5b shows with different colors the communities found in the network by the community detection algorithm. To improve the rendering, Fig. 5b does not take into account the Euclidean metrics in the node and link disposition. Modularity  $M$  (Newman, 2006) for the graph is rather high at a value of  $M = 0.758$  which means that the communities are rather well defined. Although the  $M$  measure is not without drawbacks, it still provides a rather clear-cut indication of the significance of the network's community structure.

## Conclusion

In this article we have proposed an original model for the construction of social networks having a spatial dimension. We started from the random geometric graph model and we added a few ingredients in order to generate networks that possess most of the statistical features shown by actual spatial social networks. The main idea is to attribute a limited amount of energy to nodes, the same for all of them. Nodes can spend this resource to link to other nodes as a function of their Euclidean distance, longer links being more expensive

than shorter ones. In this way we obtain networks that do indeed look similar in many ways to actual ones from the point of view of their statistical features. In particular, the modeled networks have high clustering, positive degree correlation, and the presence of community structure. Moreover, properties such as clustering and assortativity can be tuned to some extent by changing the parameters  $E$  and  $R$ . The degree distribution function is peaked due, in part, to spatial constraints but especially because of the homogeneous distribution of energy and radii among the nodes. This consideration suggests ideas for further research with the purpose of getting more realistic social networks. For example, one could assume that nodes are not placed at random on the space, in order to form even more clustered networks and have more community structures. Furthermore, it is reasonable to consider non-constant distributions of the energy among the nodes which would probably produce some more connected individuals and thus a broader degree distribution. The linking process is bilateral in the present version, i.e. both partners must pay the same amount of energy to create the connection. One-way links could also be considered and the model could be extended to make it dynamical allowing for link suppression as well as link formation.

## Abstract

With the emergence of multi-robot systems in the field of robotics there is a need for new approaches for modeling and investigating the behavior of robotic systems. Formal verification is a well-known mathematical method which has been used for decades in order to expose potential design faults in industrial systems. In this paper we introduce the application of formal verification techniques in the context of multi-robot systems. Applying verification techniques, we aim to prove that the collective behavior of a group of robots satisfies certain desired properties. We illustrate our approach using a simple path planning algorithm which conducts a set of robots from their initial positions to their destinations on a planar surface.

## Introduction

Multi-robot systems have the potential to solve complicated problems by their collective behavior. In recent years multi-robot systems have attracted the attention of many researchers. The challenge is to control the collective behavior of a number of homogeneous and simple robots in order to accomplish sophisticated tasks. Robustness and versatility are the main characteristics offered by multi-robot systems compared with single robot systems.

The path planning problem for multi-robot systems is of great importance. The objective is to find, or construct a trajectory for each robot to start moving from its initial position toward its destination while avoiding collisions. Path planning for mobile robots has been mainly addressed in the literature from two different aspects. The first approach is to construct trajectories for robots and move them along the predefined trajectories (Laumond, 1998; Luigi Biagiotti, 2009; Saska et al., 2006). The second approach is the algorithmic approach, in which robots use an algorithm to find a way toward their destinations (Jain et al., 2010; min Han, 2007; Pamosoaji and Hong, 2011). Furthermore, existing analysis approaches for robotic systems are mostly focused on the behavioral analysis of individual robots. However, with the increasing popularity of multi-robot systems new approaches are required to analyze the collective behavior of these systems.

In the context of the algorithmic approach to path planning, we propose a new method for behavioral analysis of multi-robot systems. In this approach, a well-known formal verification technique called model checking (Baier and Katoen, 2008) is applied to formally analyze the behavior of a robotic system. Model checking is an algorithmic approach which verifies the validity of a desired system property against a high-level model of the system. Model checking algorithms exhaustively explore all possible behaviors specified by the system model and check whether this model meets the given requirement. This technique is now applied to industrial software/hardware systems in order to verify the correctness of their behavior against a set of requirements. In this paper, we apply it for the analysis of a multi-robot system. The advantage of our approach is that it provides a systematic methodology for modeling and analyzing the collective behavior of a group of robots.

Fig. 1 depicts an overview of our approach. Given an informal specification of a path planning algorithm and the way robots realize this algorithm, we specify a formal model of the robotic system as a set of communicating processes in the mCRL2 language (Groote et al., 2009). Moreover, desired properties of the system are formalized in a mathematical language. In particular, we use the modal  $\mu$ -calculus (Groote and Mateescu, 1999) for property specification. The verification procedure verifies the formalized property against the system model. If the property is satisfied by the model, the verification procedure will respond with a “Yes”. Otherwise, a “No” response is returned. In this case, a counterexample is also generated which describes a situation that the property is violated by the model. We apply the mCRL2 toolset (Cranen et al., 2013) for verification of our case study.

*Related work* The application of formal methods in the context of robotic systems has been studied in different research works. Most of these works focus on constructing paths in a robot’s workspace that satisfy properties specified in a mathematical language. Given an initial position of a robot in its workspace and a requirement specified in linear temporal logic (LTL), (Fainekos et al., 2005) apply a

Figure 1: Overview of the Approach

discretization technique to generate a continuous trajectory that satisfies the LTL formula. In this method model checking tools are used for constructing trajectories. The work in (Kress-Gazit et al., 2009) describes an approach for generating a robot controller that guarantees the satisfaction of a given LTL property in all execution scenarios in certain execution environments. It is assumed that the behavior of robot's environment is specified as another LTL formula.

(Fainekos, 2011) proposes a diagnostic approach. First, they define a notion of closeness for properties specified in LTL. For an LTL property violated by the specification of the system they aim to find minimal changes to the formula that makes it satisfiable.

In (Quottrup et al., 2004) a high-level description of a timed automata-based approach for modeling and verification of a multi-robot system is provided. Due to a high level of abstraction only movements of robots are considered in the analyses. Moreover, they do not analyze concrete path planning algorithms. They apply this high level approach to evaluate certain characteristics of a robotic system (e.g., shortest time required by a robot moving in arbitrary directions to arrive at its destination) and construct paths to a destination using model checking evidence.

However, in this paper we include information about the sensing mechanisms of robots and their movements in our analysis. Hence, compared to the timed automata-based approach we investigate a lower level of abstraction. Our approach also offers a high-level language for specifying robotic systems. Moreover, the main objective of this approach is to prove that certain properties are valid/falsified in a system and provide efficient feedback to the designer of a robotic system.

**Overview** In section *System Specification* we specify the main characteristics of the robotic system that we consider as a case study in this paper. In section *Validation Properties* we discuss the types of properties that we aim to validate. Main features of our analysis approach are explained in section *mCRL2 & the Modal  $\mu$ -calculus*. We apply this approach in sections *Modeling a Multi-Robot System* and *Verification* to model and verify our case study. *Conclusion* includes some concluding remarks and suggestions for future research.

## System Specification

We introduce a simple multi-robot system which we use as a case study throughout the paper. In particular, the physical environment in which robots perform their tasks, main features of the robots (regarding their moving and sensing abilities), and the algorithm that guides robots movements are discussed in this section.

**Workspace** We assume that robots move on an unbounded planar surface. There are no static obstacles on the surface and robots are the only dynamic obstacles in this setting.

**Robots** Robot platforms designed for multi-robot applications such as (Bristeau et al., 2011; Mondada et al., 2003) assume that robots need limited computational resources to process their path planning algorithm. On the other hand, these robots are equipped with advanced hardware, e.g., sensors, and processors, to communicate with their environment or perform complicated tasks, e.g., transport heavy objects.

In our case study we consider an algorithm that can be realized by robots using limited resources. We assume that robots are capable of performing translation movements to move toward their destinations. Each robot can also perform in-place rotation movements (e.g., when facing an obstacle) in order to change its direction of movement. Moreover, each robot is only aware of the position that it currently occupies and the location of its destination. Every robot has an embedded sensing device which is capable of detecting obstacles in its range of sense.

**Algorithm** A robot starts from an initial position and tries to move toward its destination while actively scanning its range of sense for potential obstacles. Whenever a robot senses the presence of an obstacle in its sensing range, it performs an in-place 90-degree counter-clockwise rotation and scans its surroundings along the new direction. This mechanism is repeated until a safe direction is found.

It should be noted that the reactions of the robots are not affected by the actual positions of obstacles. When a robot finds a safe direction, it moves along that direction, steers itself to the destination, and repeats the path finding procedure until it arrives at its destination. In our analyses we do not make any assumptions about the relative processing rate of the robots. In other words, robots can perform their tasks with different processing rates. The same approach can be adapted to systems consisting of robots with identical processing rates.

## Validation Properties

In this section we describe several kinds of desired properties for a path planning algorithm. We aim to check for absence of deadlock, absence of collision, and reachability of robots to their destinations for a given path planning algorithm.

Figure 2: Sensing range for a specific position and movement direction

In order to perform such checks in a robotic system it is required to include information about timing, details of movement trajectories, accuracy of sensors, and shapes of the robots. To make our analyses feasible, we try to keep these details to a minimum. In our analyses we consider a specific abstraction of the robots workspace and robots behavior introduced in *System Specification*.

We assume that the robots workspace is a two dimensional grid which is uniformly partitioned into disjoint cells. Thus each cell in this setting can be characterized by a pair  $(x, y)$ . Assuming a specific position as the origin of the grid, for each robot the workspace is the following:

$$W = \{(x, y) | x, y \in \mathbb{Z}\}$$

Robots are modeled as objects without any specific shape. Each robot occupies a specific cell on the grid at each moment in time. We assume that robots can perform translation movements along vectors from the following set:

$$D = \{(i, j) | i, j \in \{-1, 0, 1\} \wedge (i, j) \neq (0, 0)\}$$

Translation movements to a neighboring cell are assumed to be atomic events without any time duration. Moreover, performing an in-place rotation by a robot does not change the configuration of the system.

We abstract from the complexities of the sensing mechanism and the way robots realize it. We assume that sensing is an atomic action. Performing this action, robots check for presence of obstacles in their range of sense. The sensing range is assumed to be one cell ahead from a robot's current position along the robot's next movement direction. In Fig. 2 the gray cell depicts the sensing range for a robot in the cell  $(0, -1)$  which intends to move along  $(-1, 1)$ . Sensors are assumed to be accurate and provide correct information.

Finally, we assume that sensing and moving are the only actions robots perform to realize a path planning algorithm. These actions are performed by robots in an infinite loop. Robots that arrive at their destinations can still sense their surroundings. In what follows we explain several properties that can be useful in the context of a path planning algorithm.

**Deadlock-freeness** Checking for absence of deadlock is one of the general checks that can be performed. Performing this check we can detect problematic situations in the

system where no further action can be performed by robots. As mentioned earlier, in our sketched system robots can always sense their surroundings. Thus, in this case deadlock freedom easily follows from the system specification. However, this check could be useful in general.

**Collision-freeness** For a given path planning algorithm, it is desirable to check that for all trajectories calculated by the algorithm, robots will never collide with an obstacle (which could be another robot). Considering our abstraction of the workspace and robots movements, this means that robots should not share a cell on the grid with another object.

**Reachability** The ultimate goal of a path planning algorithm is to guide robots to their destinations. We check whether robots can reach their desired destinations in a finite number of steps. It is also possible to define a limit on the number of steps that a robot takes before reaching its goal.

As each robot can prevent other robots from reaching their destinations, we are also investigating reachability while reaching the goal can be prevented by other robots for infinitely many times.

## mCRL2 & the Modal $\mu$ -calculus

In this section we explain the details of our analysis approach depicted in Fig. 1. In section *Labeled Transition Systems* we describe labeled transition systems as a means for modeling and analyzing the behavior of systems. In section *The mCRL2 language* we introduce mCRL2 as a high-level language for specifying labeled transition systems in a compositional manner. We use this language to capture the behavior of multi-robot systems by specifying and composing the behavior of its components. The modal  $\mu$ -calculus is the property specification language used in our approach which is briefly explained in section *The modal  $\mu$ -calculus*.

### Labeled Transition Systems

Modeling and analyzing the behavior of systems with labeled transition systems (LTS) is a common technique. A labeled transition system is a directed graph with a set of states, i.e., graph nodes, and a set of transitions, i.e., graph edges. States of an LTS correspond to system states. Transitions are labeled by actions and show the evolution of the system when executing a specific action. Labeled transition systems have an initial state which is depicted by an incoming arrow.

Fig. 3 is a simple LTS which specifies the following behavior for a system. Starting in the initial state an  $a$  action is performed. Then the system non-deterministically chooses to perform an  $a$  or  $b$ . Performing an  $a$  will result in a state where no further action can be performed by the system. Performing a  $b$  means that the left branch is executed. After the  $b$  action is done the system will perform  $a$  forever.

Figure 3: A simple labeled transition system

## The mCRL2 language

Modeling systems behavior with LTSs does not scale to complex systems. High-level languages can be used to describe complex LTSs. We use the mCRL2 language for this purpose. In this language LTSs are described as processes. Data specification and process specification are the main aspects of the language.

**Data specification** The data specification subset of the language allows the user to use the built-in data types (e.g., booleans, natural numbers) or to define and manipulate her own system-specific data types. For instance, in our case study we need two data types to specify the position of each robot and movement vectors. In the mCRL2 syntax we have:

```
sort Pnt = struct P(X:Int,Y:Int);
Dir = struct D(I:Int,J:Int);
```

 (1)

Each variable of type Pnt corresponds to a cell on the grid. Instances of Pnt can be constructed by applying the constructor P. For an instance p of type Pnt the first and second element of the pair can be accessed through the application of the projection functions X and Y, respectively. The same argument is applicable to Dir. In our modeling we always use instances d of Dir such that  $I(d), J(d) \in \{-1, 0, 1\}$ .

Useful operations on data types can be defined as functions. Each function is specified by its name, types of arguments and return type, and a set of equations describing the relation between the input(s) and output of the function. We illustrate this with an example:

```
map NextPos:Pnt # Dir -> Pnt;
var p:Pnt, d:Dir;
eqn NextPos(p,d)= P(X(p)+I(d), Y(p)+J(d));
```

 (2)

Given the current position of a robot and its next movement direction, NextPos computes its next position. In this example, we have one equation in our equation system (preceded by eqn). The var block preceding the equation system defines the variables used in the equation. These variables are used for pattern matching. The single equation specifies that for a given position p and direction d, the return value is an instance of Pnt. The X attribute of the next position is the sum of X(p) and I(d). The Y attribute is computed in a similar way.

**Process specification** The process specification aspect of the language provides a compositional way for system behavior specification. Actions are the main building blocks of processes. We assume that actions are atomic events without any time duration. Actions can also carry data parameters. For the specification of a robotic system, we can define an action which mimics a single step movement of a robot. The parameter of this action specifies the movement vector.

```
act move:Dir;
```

In order to achieve complex behaviors or communication patterns we can combine actions sequentially, in parallel, or make a non-deterministic choice between a (possibly infinite) set of actions. We can also let data values affect the behavior of a process by adding conditional expressions to processes.

The non-deterministic choice between processes  $P$  and  $Q$  is denoted by  $P + Q$ . The process  $P + Q$  will behave as  $P$  or  $Q$ . The sequential composition of  $P$  and  $Q$  is denoted by  $P.Q$  and the resulting process first performs the behavior of  $P$  and then behaves as  $Q$ . The notation  $P||Q$  represents the parallel execution of  $P$  and  $Q$ . It is also possible to enforce communication between actions executed by different processes. Using this facility together with the operator  $||$ , one can force communication between  $P$  and  $Q$  for specific actions. The rest of the actions will be interleaved. Assuming that  $c$  is a boolean expression, the process  $c \rightarrow P \diamond Q$  will behave as  $P$  if  $c$  is satisfied and will behave as  $Q$  otherwise.

Using the mCRL2 language, we can specify the movements of a robot as a process. For example, a robot that takes a sequence of non-deterministically chosen right and left steps can be specified as follows:

```
proc Robot(rp:Pnt) =
  move(D(1,0)).Robot(NextPos(rp,D(1,0))) +
  move(D(-1,0)).Robot(NextPos(rp,D(-1,0)));
```

The process carries a data parameter which represents the current position of Robot. After each movement along  $D(1,0)$  or  $D(-1,0)$  the robot behaves as the Robot process with a new parameter calculated by NextPos.

One can easily influence the choices of Robot by another process, e.g., Environment. In our context this process can mimic the behavior of the environment by collecting information about the workspace and enforcing certain constraints on movements. We can establish a communication between the two processes to enforce a movement in a specific direction. To realize this communication in this example, Environment should perform an action, e.g., en\_move, which carries data parameters of the same type as move. We describe Environment as follows:

```
proc Environment =
  en_move(D(1,0)).en_move(D(-1,0)).Environment;
```

By enforcing the communication between move and en\_move and executing Robot and Environment in parallel, the required controlling mechanism will be achieved. In this way,

Figure 4: LTS for Robot | Environment with enforced communication

*move* and *en\_move* are only executed in a synchronized manner both carrying equal data parameters. In our simplified example Environment only affects the movement direction of Robot by enforcing it to move to its right and left alternately. Putting Robot and Environment in parallel will result in the LTS of Fig. 4 where action *m* represents the communication of *move* and *en\_move*.

### The modal $\mu$ -calculus

We use the modal  $\mu$ -calculus for specifying system properties. The following grammar gives the basic form of modal  $\mu$ -calculus formulae where *a* is an action.

$$\begin{aligned} \phi ::= & \text{true} \mid \text{false} \mid \neg\phi \mid \phi \wedge \phi \mid \phi \vee \phi \mid \\ & \langle a \rangle \phi \mid [a] \phi \mid \mu X. \phi \mid \nu X. \phi \end{aligned} \quad (3)$$

The operators  $\wedge$ ,  $\vee$ , and  $\neg$  have their usual meanings. The formula  $\langle a \rangle \phi$  is valid in a state of an LTS when an action *a* can be performed such that  $\phi$  is valid after this action *a* has been done. The formula  $[a] \phi$  is valid in a state if all possible executions of action *a* lead to a state where  $\phi$  holds.

The formulae  $\mu X. \phi$  and  $\nu X. \phi$  are the minimal and maximal fixed points, respectively. In both cases, *X* usually occurs in  $\phi$ . The property  $\mu X. \phi$  is valid for all the states in the smallest set *X* that satisfies ' $X = \phi_s$ '. Similarly,  $\nu X. \phi$  is valid for all the states in the largest set *X* that satisfies ' $X = \phi_s$ ' where  $\phi_s$  represents all states where  $\phi$  is valid. Other capital letters (e.g., *Y*) can also be used instead of *X*.

As an example consider a setting with parameterless actions  $\{\text{move}, \text{sense}\}$ . The property  $\mu X. ([\text{sense}]X)$  is valid if *sense* is executed for a finite number of times. In other words, *move* is unavoidable (unless a deadlock occurs). The property  $\nu X \mu Y. ([\text{move}]X \vee [\text{sense}]Y)$  specifies that any subsequence of consecutive *sense* actions should be finite.

It is often useful to use a variant of the grammar in Eqn. 3 which allows the occurrence of multiple actions or a sequence of actions in a modality. For this purpose regular formulas are used within modalities. The formula *true* represents the set of all actions and  $\cup$  (union),  $\cap$  (intersection), and  $\neg$  (complement with respect to the set of all actions) can be used to specify action formulas. Regular formulas extend action formulas to allow the use of sequences of actions in modalities. For instance for a subset of actions  $\alpha$ ,  $\alpha^*$  denotes any sequence of actions from  $\alpha$ .

Since actions can carry data parameters, we need ways to refer to data values in formulae. As an example consider the

Figure 5: Robot and Environment processes

set of actions  $\{\text{move}, \text{sense}\}$  both carrying one data parameter of type *Dir*. Data can be introduced to modal formulae referring to *move* and *sense* using existential or universal quantifiers. Quantification can be used within modalities. For instance  $\forall d : \text{Dir} : (\neg \text{move}(d))^* \phi$  says that as long as there is no move in any direction,  $\phi$  should hold. Quantifiers can also be used outside the scope of modalities with their standard meaning. For instance  $\forall d : \text{Dir}. [\text{move}(d)] \phi$  is true if  $\phi$  holds after performing *move* in any direction. We can also store and process data values in fixed points. Using this feature it is possible for instance to specify constraints on the number of certain events. Consider the following formula:

$$\mu X(p : \text{Pnt} = P0). (\forall d : \text{Dir} [\text{move}(d)] X (\text{NextPos}(p, d)) \vee (X(p) > Y(p)))$$

Here *p* records the current position of the robot and is initially set to the *P0* (the initial position). The property says that after finite number of movements the robot should be in a certain part of the grid where  $X(p) > Y(p)$  holds.

We refer the interested reader to (Groote and Mateescu, 1999) for a more detailed explanation of the modal  $\mu$ -calculus and its semantics.

### Modeling a Multi-Robot System

In this section we elaborate on the simple modeling scheme we introduced in the previous section to formalize the multi-robot system described in section *System Specification*. Fig. 5 depicts a schematic view of our modeling approach. For a system consisting of *n* robots we specify *n* + 1 processes, i.e., *n* robot processes and 1 environment process, in mCRL2 and put them in parallel. This scheme conforms to our description in *System Specification*, i.e., robots communicate with the environment but they do not have direct communication among themselves.

Each process carries and manipulates certain data parameters. Every robot process carries parameters which indicate its current position and the (potential) direction of the next move. We assign a unique identifier to each robot process so the environment process can distinguish them when performing communications. The environment process carries data parameters to record the current position of all the robots. Since the destinations of the robots are not affected

by the dynamics of the system we model them as global parameters. For instance for Robot1 from Fig. 5 we can specify the destination as the position (2, 3) as follows:

```
map PD1:Pnt;
eqn X(PD1)=2;Y(PD1)=3; (4)
```

In our case study we assume that the system consists of identical robots. Thus, the processes we use to describe their behavior only differ in the unique parameter that is used for the identification of the robots. This approach can be adapted to systems consisting of robots with nonidentical path planning algorithms. For the sake of simplicity we study a system with two robots in this paper. The following definition specifies a data type with two unique instances which we use for robots identification.

```
sort ID = struct id1|id2;
```

In what follows we explain the mCRL2 processes that we use to describe the robots and the environment.

**Robots** In our abstraction of the robotic system, each robot scans its surroundings and performs movements in an infinite loop. Thus, robot processes can be specified in terms of actions *rs* (sense) and *rm* (move).

We enforce a communication on *rs* with the environment to collect information about the presence of obstacles. A robot performs *rs* providing its unique identifier and the next movement direction. Performing *rs* a robot should be able to react to both outcomes of the performed check, i.e. presence or absence of obstacles. We specify *rs* as follows:

```
act rs:ID # Dir # Bool; (5)
```

Scanning the range of sense along vector *d* by a robot identified by *id1* can be modeled as a nondeterministic choice between a “Yes” or “No” response for presence of obstacles, i.e., *rs*(*id1*,*d*,*true*)+*rs*(*id1*,*d*,*false*).

To establish a communication on *rs*, the environment process should perform an action, e.g., *es*, with identical parameter values. Given the movement direction of the robot, if the environment does not find an obstacle in the range of sense it will perform *es*(*id1*,*d*,*false*). Next, the robot will perform a move action along the direction vector. Otherwise, the environment will perform *es*(*id1*,*d*,*true*) and the robot should not move.

A robot identified by *id1* performs *rm*(*id1*,*d*) to declare its movement along the vector *d*. We enforce a communication between the robots and the environment on this action. In this way the environment can calculate the new position of the moving robot and update its information. The following process describes the behavior of a robot identified by *id1*. The process Robot2 can be specified in a similar way.

```
proc Robot1(p:Pnt,d:Dir) =
sum b:bool. rs (id1,d,b).b ->
  Robot1(p,NextDir(id1,d,p,b)) <>
  rm(id1,d).Robot1(NextPos(p,d),
    NextDir(id1,d,NextPos(p,d),b));
```

The syntax **sum** *b*: **bool**. *rs* (*id1*,*d*,*b*) is a shorthand for *rs*(*id1*,*d*,*true*)+*rs*(*id1*,*d*,*false*). The conditional statement in Robot1 indicates that after performing *rm* the same behavior is repeated with new position and direction parameters calculated by *NextPos* (see Eqn. (2)) and *NextDir* functions, respectively. On the other hand, the presence of obstacles only causes an in-place change of direction. The following expressions partially specify *NextDir*:

```
map NextDir:ID # Dir # Pnt # Bool -> Dir;
var cp:Pnt, cd:Dir, b:Bool;
eqn (cp!=PD1) -> NextDir(id1,cd,cp,false) =
  D(sgn(X(PD1)-X(cp)),sgn(Y(PD1)-Y(cp)));
  (cp!=PD1) -> NextDir(id1,cd,cp,true) =
  D(-Y(cd), X(cd));
  (cp==PD1) -> NextDir(id1,cd,cp,b) = D(0,0);
```

In this specification *sgn* is a function that extracts the sign of its argument and *PD1* is Robot1’s destination (Eqn. (4)). The notations *==* and *!=* denote data equality and inequality. Two instances *p1*,*p2* of *Pnt* are equal if and only if *X*(*p1*)=*X*(*p2*) and *Y*(*p1*)=*Y*(*p2*). The first and second rule of the equation system determine the next movement direction for the first robot when it is not at its destination. Absence of obstacles in the last scan activates the first rule and the next direction is calculated in order to guide the robot closer to its destination. Presence of an obstacle in the last scan activates the second rule which mimics a 90-degree counterclockwise rotation. The last rule sets the direction to (0,0) when the robot arrives at its destination. The complete specification can be derived by describing a similar behavior for *id2*.

Fig. 6 depicts the LTS described by Robot1 where each state is labeled by the data parameters carried by the process in that state.

**Environment** The Environment process records the position of the robots and performs the actions *es* and *em* in order to establish the required communications with the robot processes. The following mCRL2 syntax describes this process:

```
proc Environment(p1:Pnt,p2:Pnt) =
sum id:ID, d:Dir.es(id,d,Sense(id,p1,p2,d)).
  Sense(id,p1,p2,d)->
    Environment(p1,p2)<>
    (id==id1) ->
      em(id1,d).Environment(NextPos(p1,d),p2) +
    (id==id2) ->
      em(id2,d).Environment(p1,NextPos(p2,d));
```

The summations over the data types *ID* and *Dir* indicate that this process can establish a communication with any robot on the action *es* to perform a check for obstacles along direction *d*. The function *Sense* performs this check. If a movement is possible, Environment will update its information with the new position. Otherwise it will repeat the same

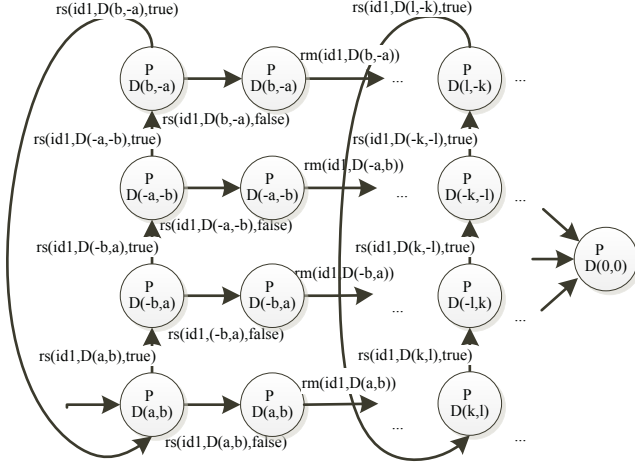

Figure 6: LTS description for Robot 1

behavior. A partial specification of Sense is as follows:

```

map Sense:ID # Pnt # Pnt # Dir -> Bool;
var cp1, cp2:Pnt, cd:Dir;
eqn (PD1!=cp1) -> Sense(id1, cp1, cp2, cd) =
    (cp2==NextPos(cp1, cd));
    (PD1==cp1) -> Sense(id1, cp1, cp2, cd) = false;

```

The first rule checks for presence of obstacles when the first robot is not in its destination. It simply checks whether a movement in the specified direction will cause a collision with the second robot (see Fig. 2). Since robots can only move along (0, 0) after arriving at their destinations, the second rule always declares absence of obstacles when Robot 1 arrives at its destination. The complete specification can be derived by describing a similar behavior for id2.

Finally, we initialize the specified processes and put them in parallel to achieve a model for the system (Fig. 5). To this end we use the following mCRL2 syntax:

```

init
allow({m, s}, comm({rm|em -> m, rs|es -> s},
    Robot1(P01, D01) || Robot2(P02, D02) ||
    Environment(P01, P02)));

```

The **comm** operator is used to establish communication between **rs** and **es** and renames this communication to a single action (**s**). The **allow** operator enforces the specified communications. In other words it blocks non-synchronous execution of **rs** and **es**. The actions **rm** and **em** are treated in the same way. The initial position and direction parameters, e.g., P01, can be specified similar to Eqn. (4).

## Verification

In what follows we first formalize the properties from *Validation Properties* in the modal  $\mu$ -calculus. We report on the results and observations we achieved on verifying these

properties against the specification discussed in the previous section. We applied the mCRL2 toolset for verification.

**Deadlock-freeness** In any reachable state of the system it is possible to perform an action:

$$[true^*](true)true \quad (7)$$

**Collision-freeness** Trajectories calculated by the algorithm will not cause a collision for two robots initially at P01 and P02, i.e., robots will not share a cell on the grid:

$$\begin{aligned}
 &\nu X(p_1 : Pnt = P01, p_2 : Pnt = P02). \\
 &((\forall id : ID, d : Dir. \neg m(id, d)]X(p_1, p_2)) \wedge \\
 &(\forall d : Dir. [m(id1, d)]X(NextPos(p_1, d), p_2)) \wedge \\
 &(\forall d : Dir. [m(id2, d)]X(p_1, NextPos(p_2, d))) \wedge \\
 &(p_1 \neq p_2)
 \end{aligned} \quad (8)$$

**Reachability** Robot1 (initially at P01) should reach its destination (PD1) with a finite number of movements:

$$\begin{aligned}
 &\mu X(p : Pnt = P01). \nu Y. ((\nexists d : Dir. m(id1, d)]Y \wedge \\
 &(\forall d : Dir. [m(id1, d)]X(NextPos(p, d)))) \vee (p == PD1))
 \end{aligned} \quad (9)$$

Applying the mCRL2 toolset we verified these properties against the model of the system. The properties (7) and (8) hold for any combination of different initial and destination positions for the robots chosen from the following set:

$$TestPoints = \{(x, y) | x, y \in \{0, \dots, 5\}\} \quad (10)$$

However, reachability does not hold in general. For instance, we identified the counterexample in Fig. 7. Movements of the first and second robot are depicted by filled and dashed arrows, respectively. The numbers denote the order of the performed moves. Initial and destination cells are marked by circles and flags, respectively. In this case the second robot moves relatively slowly compared to the first robot and it stops at the destination of the first robot. This causes a livelock in the first robot's behavior, i.e., it will perform the same sequence of actions without making any progress.

In an attempt to characterize the occurring problem we introduce a new notion of reachability where infinite movement steps are allowed when at least one of the robots is "close" to the destination of the other robot. The following formula formalizes this property:

$$\begin{aligned}
 &\mu X(p_1 : Pnt = P01, p_2 : Pnt = P02). \\
 &\nu Y(p'_1 : Pnt = p_1, p'_2 : Pnt = p_2). \\
 &(((\forall d : Dir. [m(id1, d)] \\
 &(((Near(p'_2, PD1) \vee Near(NextPos(p'_1, d), PD2)) \wedge \\
 &Y(NextPos(p'_1, d), p'_2)) \\
 &\vee (!Near(p'_2, PD1) \wedge !Near(NextPos(p'_1, d), PD2))) \wedge \\
 &X(NextPos(p'_1, d), p'_2))) \wedge \\
 &(\forall d : Dir. [m(id2, d)]Y(p'_1, NextPos(p'_2, d))) \wedge \\
 &([\nexists id : ID, d : Dir. !m(id, d)]Y(p'_1, p'_2))) \vee \\
 &(p_1 == PD1))
 \end{aligned}$$

Figure 7: A counterexample for reachability

The function Near is defined as follows where abs is the built-in absolute value function:

```
map Near:Pnt # Pnt -> Bool;
var p1,p2:Pnt;
eqn Near(p1,p2) = (abs(X(p1)-X(p2)) <= 2 &&
                  abs(Y(p1)-Y(p2)) <= 2 );
```

This property is satisfied by the system described in the previous section for any reasonable combination of initial and destination positions from Eqn. (10).

## Conclusion

In the context of high level algorithmic approach to the path planning problem we studied ways to analyze multi-robot systems in a systematic way. The final goal is to verify a set of desired properties against a high-level model of a system and provide efficient feedback to the designer of the system.

We have introduced an approach based on process algebras for modeling and analyzing path planning algorithms. We have used the mCRL2 language and the modal  $\mu$ -calculus for describing a multi-robot system and its properties. The mCRL2 toolset has been used for the verification of these properties. We have applied this approach to investigate the correctness of a set of useful properties in a simple multi-robot system. Our observations show that for a simple path planning algorithm useful properties can be verified with the proposed approach efficiently (about one minute for each property on a standard desktop computer).

We envisage applying our approach to systems with more sophisticated path planning algorithms. Applying this approach to systems consisting of a large number of robots can also be considered as future work.

# Autocatalysis Before Enzymes: The Emergence of Prebiotic Chain Reactions

Nathaniel Virgo, Takashi Ikegami

Ikegami Laboratory, University of Tokyo  
nathanielvirgo@gmail.com

## Abstract

How could complex, enzyme- or ribozyme-like molecules first have arisen on planet Earth? Several authors have suggested *autocatalytic cycles* as a partial answer to this question, since such reactions exhibit the life-like property of exponential growth while being composed of relatively simple molecules. However, a question remains as to the likelihood of an autocatalytic cycle forming spontaneously in the absence of highly specific catalysts. Here we show that such cycles form readily in a very simple model that includes no direct catalysis reactions. Catalytic effects nevertheless emerge as properties of the reaction network. This suggests that the conditions for the formation of such cycles are not difficult to achieve. The resulting cycles solve the problem of specificity not by being small and simple but by being large and complicated, suggesting that early prebiotic metabolisms could have been extremely complex. We predict that this phenomenon can be reproduced in wet chemistry. We discuss the challenges involved in this, as well as the implications for how we view the origins of life.

## Introduction

A necessary requirement for biological metabolism is *autocatalytic kinetics*, i.e. the ability of a set of chemical species to increase its own rate of production. Without the ability to positively influence the production of its own chemical components, the prebiotic equivalent of a living organism would be able neither to reproduce nor to maintain its own composition over time. In this paper we investigate the possibility that the earliest proto-metabolisms achieved this through a mechanism known as an autocatalytic cycle.

In this paper we present a highly simplified model of a simple organic polymer chemistry operating away from thermodynamic equilibrium. This model is extremely simple, consisting only of basic synthesis and decomposition reactions, with no catalytic kinetics assumed *a priori*. We find that autocatalytic cycles form readily in such a system, suggesting that the chemistry in which the first steps toward metabolism took place could have been much simpler than generally supposed. The networks that emerge in our model are complex, consisting of many interlinked catalytic and autocatalytic cycles. The highly interconnected nature of

these autocatalytic subnetworks means that a reaction involving one of the intermediates is likely to produce another intermediate, thus overcoming the much-discussed problem of specificity in autocatalytic cycles. This suggests that complex autocatalytic reaction networks formed from simple molecules can be produced much more easily than simple networks composed of complex “replicator” molecules.

Because the requirements for this phenomenon are so easy to meet, it should be possible to observe it experimentally, in prebiotic chemistry experiments along the lines of the Miller-Urey experiment or HCN polymerisation. To achieve this one would need to change the conditions so that the breakdown of polymers via hydrolysis or oxidation occurs in the same system as their synthesis, at a comparable rate. This simultaneous build-up and break-down of polymers is analogous to anabolism and catabolism in biology. We comment on the potential implications of such a result, and the challenges that would be involved in attaining it.

It is worth pointing out a major difference between our model and one of the predominant existing approaches to explaining the origin of biological autocatalysis. As discussed below, there are many studies that model the emergence of autocatalysis in networks of reactions between peptide or RNA-like molecules, via a mechanism known variously as reflexive autocatalysis, autocatalytic sets or RAF sets. This work has shown that autocatalysis is easy to achieve via this mechanism even if the reaction networks are chosen at random rather than having autocatalysis “designed” into them (Kauffman, 1986); and that such autocatalytic sets are capable of evolution by natural selection via an attractor-based heredity mechanism, even in the absence of specific information-carrying molecules (Vasas et al., 2012).

However, this definition of autocatalysis presupposes the existence of single-step catalysis reactions, and therefore entails an assumption that the molecules involved are complex enough to behave as enzymes. Because our aim is to explain the emergence of such complex molecules from simpler reactants, we focus instead on a different mechanism: the *autocatalytic cycle* or *branching chain reaction* (King, 1978).

For our purposes, a branching chain reaction may be de-

Figure 1: (a) Schematic of the reductive citric acid cycle, redrawn from Morowitz et al. (2000). The branching step is the splitting up of citrate into oxaloacetate and acetyl CoA, which is then transformed into a second oxaloacetate, so that its concentration doubles on every turn of the cycle. (b) The mechanism of the formose reaction, as proposed by Breslow (1959). The branching step is the decomposition of an aldohexose into two molecules of glycolaldehyde. The formose reaction has been observed experimentally, without the use of biological catalysts.

defined as a net chemical reaction, at least one of whose products is also an intermediate. This allows the concentration of intermediates to build up over time, which under the right conditions can lead to exponential growth. Such reactions are not uncommon and are often the mechanism behind combustion and explosive reactions. A more formal definition of this type of autocatalysis is given by Andersen et al. (2012). In the classification of Plesson et al. (2011), this definition includes direct, indirect and autoinductive forms of autocatalysis.

Some known examples of autocatalysis via branching chain reactions are shown in Fig. 1 and 2. This definition is similar in spirit to that of an autocatalytic set, but in our case the catalysis mechanism emerges from the system's dynamics, rather than being a property of individual molecules.

Autocatalytic cycles have been hypothesised as playing an important role in the origins of life. Wächtershäuser (1988), and later Morowitz et al. (2000) proposed the *reductive citric acid cycle* (Figure 1a) as a possible means by which molecules such as sugars, lipids and amino acids could have been generated on the early Earth. The citric acid cycle is important in modern biology but its intermediate steps are catalysed by enzymes. Wächtershäuser's argument was that inorganic surface catalysts might have been able to play the same role on the early Earth. Morowitz et al. argued that the reductive citric acid cycle might be unique, in the sense of being the only autocatalytic cycle that could lead to the complexity of modern life on an Earth-like planet.

Figure 2: Some other known examples of autocatalysis via chain reactions. (a) A few of the most important reaction steps in the early stages of the combustion of H<sub>2</sub>, demonstrating autocatalysis via a more complex network than a single cycle. H<sub>2</sub> and O<sub>2</sub> can be mixed without reacting, but due to this mechanism they will react very rapidly after an initial spark produces small quantities of H and O. (b) Template replication is a special case of chain reaction autocatalysis. Here, an AB dimer catalyses the formation of another AB dimer through complementary base pairing. Figure 2b is taken from Virgo et al. (2012), in which a physical instantiation of template replication was demonstrated using macroscopic “monomers” floating above an air table.

These ideas have been criticised on the grounds that it would be difficult to find mineral catalysts that would catalyse every step in this relatively complex cycle (Orgel, 2000) without also catalysing side-reactions that would reduce the replicator's specificity to a non-viable level (Szathmáry, 2000). This latter problem must be solved by any approach to the origins of life. In any autocatalytic chemical system there will be reactions that contribute to the autocatalytic network (branching reactions and propagating reactions) and reactions that deplete its constituents (terminating reactions). If the latter dominate then growth will not occur.

In this paper we offer solutions to these problems. King (1982) gave a heuristic argument that the formation of autocatalytic cycles is very likely in systems that are driven by a flow of energy across their boundary but closed to matter flow. This is because the products of any reaction will eventually be recycled, and this recycling process has a high probability of forming part of an autocatalytic cycle. Our model confirms that this phenomenon can occur in very simple driven systems, even if the system is not completely closed to matter flow. This suggests that there may be a great number of simpler autocatalytic systems that could have preceded the reductive citric acid cycle, perhaps ultimately leading to the production of complex organic molecules that could play the role of enzymes.

In the same paper, King argued that autocatalytic cycles with many intermediate species are statistically unlikely to be viable, in the sense of being able to grow exponentially. This is because every step in an autocatalytic cycle is vulnerable to side reactions. Every reaction step may be assigned a number between 0 and 1 representing its specificity, and it can be shown that the cycle is only viable if the product of the specificities passes a threshold. Hence, all else being equal, a cycle with many steps is less likely to be viable than one with only a few. However, in our model we observe fairly large autocatalytic systems that are composed not of a single cycle but of many intersecting catalytic and autocatalytic cycles. It seems that such systems avoid the need for specificity simply by including such a large number of species that the production of molecule that *isn't* part of the autocatalytic network is comparatively low.

Our model shows that branching chain reactions occur rather easily under certain conditions. Essentially all that is needed is the simultaneous presence of synthesis reactions (such as polymerisation) and decomposition reactions (such as oxidation or hydrolysis), as well as a source of free energy that causes some reactions to be favoured over others. These processes are closely analogous to anabolism and catabolism in a living cell. On the early Earth there were a wide variety of potential energy sources (Deamer and Weber, 2010) as well as, presumably, a wide variety of environments of varying temperatures, pressures, pH values, redox conditions etc., making it fairly likely for such conditions to be satisfied somewhere on the planet. Such conditions should also be relatively easy to achieve experimentally.

Below we survey the two main existing approaches to the emergence of autocatalysis within the field of ALife, before presenting our own model and its results. This is followed by an extended discussion of how this phenomenon fits into our picture of the early Earth, as well as the challenges involved in demonstrating it in wet chemistry experiments.

### Artificial Chemistry approaches to Autocatalysis

Our aim in this work is to apply an “artificial chemistry” methodology to the question of how autocatalytic cycles can arise in prebiotic chemistry. In this section we briefly survey previous work that has had similar aims. This previous work has two main starting points: the work of Kauffman (1986) and the work of Fontana and Buss (1994).

A central work in the metabolism-first school of the origins of life is the model of Kauffman (1986), who showed that, even if the reaction scheme of an artificial chemistry is chosen completely at random, the probability of a collectively autocatalytic set of protein-like polymers becomes high as the number of species present increases. This is an important idea, because it implies that under the right circumstances, the emergence of something akin to biological metabolism might be almost inevitable, even without the organising force of natural selection. With good reason, this

work has spawned a multitude of successors.

However, it must be stressed that, due to its origins in a theory of protein interactions, this body of work assumes a particular mechanism for autocatalysis, which can only occur in relatively complex chemistries. This mechanism relies on the idea that the molecules involved are each able to behave like enzymes, selectively catalysing some reactions but not others in a way that can be modelled as a single-step reaction. This would require the monomers to be of a certain level of complexity. Our aim is to show that similar phenomena can occur without assuming enzyme-like kinetics.

From a quite different direction, the work of Fontana and Buss (1994) looked for autocatalysis in chemistries where the molecules were represented as Lambda calculus expressions. The goal of this work was to investigate the generation of novelty through the formation of autocatalytic structures. This work also spawned a large number of successors, including the work of Ikegami and Hashimoto (1995), who looked for the emergence of autocatalysis in networks of Turing machines and tapes under a noisy environment.

Work in this sub-field tends not to include thermodynamic considerations, choosing instead to emphasise the structure of the reaction network itself. A secondary goal of our work is to investigate the impact of thermodynamic considerations on such “abstract chemistries”. In particular, in real chemistry, reactions may proceed in the forward or in the reverse direction, depending on the free energy difference between the reactants and the products. We will argue that giving the system the ability to “choose” the direction of reactions in this way is important for the emergence of autocatalysis.

### A Simple Model

We are concerned with the question of whether autocatalytic cycles, or more complex branching chain reactions, can occur in simple (non-enzymatic) organic chemistry. To do so we use a model in which a reaction network is randomly generated by allowing or disallowing cleavage and ligation reactions between polymers. A key difference between our work and previous work is that in our model no polymer can directly catalyse any reaction, so any autocatalysis that occurs must be via cycles rather than enzyme-like catalysis.

In polymer models in artificial chemistry, molecules are usually considered to consist of a string of  $m$  different types of monomer. For the sake of simplicity, in this work we set  $m = 1$ , restricting ourselves to a single monomer type, denoted A. The possible species can therefore be written  $A_1, A_2, \dots, A_n$ , where  $n$  is a maximum allowed polymer length, imposed for reasons of computational tractability. These are intended to represent molecules based on simple carbon chains, rather than complex heteropolymers such as peptides or RNA strands.

All reactions must preserve the number of monomers. We consider only reactions of the form  $A_i + A_j \rightleftharpoons A_k$ , where  $k = i + j$  is not greater than  $n$  and, to avoid duplicates,

$i \leq j$ . To generate a reaction network we must decide, for every such reaction, whether to include it in the network or not. For simplicity, following Kauffman, we simply include each reaction in the network with a constant uniform probability  $p$ , independently of every other reaction. The double arrow indicates that the forward reaction  $A_{i+j} \longrightarrow A_i + A_j$  and the reverse reaction  $A_i + A_j \longrightarrow A_{i+j}$  are always either both included in the network or both not included. This is required for consistency with thermodynamics, and as we will see, it plays an important role in the emergence of autocatalytic networks in our model.

We assume that the rate constants of all the included reactions are equal. Setting the forward rate constant to 1 without loss of generality and letting  $k$  stand for the reverse rate constant, we let each reaction  $A_i + A_j \rightleftharpoons A_{i+j}$  occur at a net rate  $R_{ij} = a_i a_j - k a_{i+j}$ , where  $a_i$  is the molar concentration of species  $i$ .  $R_{ij}$  may be positive or negative, representing a net synthesis or net decomposition reaction, depending on the concentrations of the three reactants. The justification for the  $a_i a_j$  term is that the ends of two polymer molecules must meet in order for them to undergo a ligation reaction, and we assume that the polymer tips, rather than the polymers themselves, behave like point particles in a well mixed system. (Such “mass action” assumptions are common in models of polymerisation kinetics.) The  $-k a_{i+j}$  term simply means that, for every decomposition reaction in the network, there is a constant probability per unit time that it will occur in a given molecule. We write  $R_{ij} = 0$  if the reaction is not included in the network.

This leads to the following set of dynamical equations:

$$\dot{a}_i = \phi_i + \sum_{k=1}^{i-1} R_{k,i-k} - \sum_{j=1}^i R_{ij} \quad (1)$$

where the  $R_{ij}$  are as defined above, and  $\phi_i$  represents the flux of  $A_i$  in or out of the system, as explained below. The two summation terms arise from the fact that each species  $A_i$  is involved in reactions of the form  $A_k + A_{i-k} \rightleftharpoons A_i$  as well as  $A_j + A_i \rightleftharpoons A_{i+j}$ .

### Thermodynamic properties

If we let the fluxes  $\phi_i = 0$ , the system will approach thermodynamic equilibrium. In such a state the reactions have the property of *detailed balance*, meaning that the forward and reverse rates are equal for every reaction. For a reaction  $A_i + A_j \rightleftharpoons A_{i+j}$  this occurs when  $a_i a_j = k a_{i+j}$ , or  $\log a_i + \log a_j = \log k + \log a_{i+j}$ . We may therefore define the *chemical potential*  $\mu_i$  of species  $i$  to be  $(i-1) \log k + \log a_i$ . This has the property that when the system is in thermodynamic equilibrium,  $\mu_i + \mu_j = \mu_{i+j}$ . (The usual thermodynamic definition of chemical potential would include a factor of  $RT$ , the gas constant times the temperature, which we have set to 1 for convenience.) From this we may define the Gibbs energy  $G = \sum_i \mu_i a_i$ . In accordance

with the second law,  $G$  cannot increase over time unless we allow some fluxes of matter in and out of the system. For a closed system,  $G$  is a Lyapunov function.

If we temporarily assume that every allowable reaction is included in the network ( $p = 1$ ), we can see that the equilibrium concentrations must satisfy  $a_i = k e^{C_i}$ , for some constant  $C$ , in order for detailed balance to hold for every reaction. The value of the constant  $C$  depends on the initial conditions, which stems from the fact that the total number of monomers in the system,  $\sum_i i a_i$ , is conserved. Low initial concentrations will lead to decomposition reactions being favoured, and therefore low (negative) values for  $C$ , whereas high total monomer concentrations lead to synthesis reactions being favoured. High enough concentrations lead to positive values for  $C$ , meaning that the equilibrium conditions are dominated by the longest possible polymers rather than by short ones. This phenomenon is observed in real polymer chemistries. If  $p < 1$  then it is possible for equilibrium situations to exist where this condition is not satisfied, because conservation laws arise that prevent some concentrations from becoming equilibrated with one another. However, in these cases higher concentrations still lead to longer products being favoured.

In order to observe the operation of autocatalytic cycles, the system must be held away from thermodynamic equilibrium. In real chemical systems this can be achieved in many ways. For example, by cycling the temperature or pH (both of which would effectively change  $k$  in our model), or through electrochemistry or photochemistry, which can drive reactions that would otherwise not be thermodynamically favourable. In the first set of results below we model the reactions as being held out of equilibrium by continually adding reactants and removing products, as in a flow reactor; in the second we simply start the system in an initial state far from equilibrium and observe the decrease in Gibbs energy over time.

## Results

In this section we present the results from two different simulations based on the above model. The first serves as a useful demonstration of the formation of autocatalytic cycles in driven systems, but is somewhat contrived; the second shows that autocatalytic kinetics can arise in larger, randomly-generated systems.

In our first model we set  $p = 1$ , including every reaction in the network, but we limit the size of the largest polymer. There are many ways in which the system may be held out of equilibrium; in this illustrative example we do it by letting the fluxes  $\phi_1$  and  $\phi_2$  have nonzero values, with their rates chosen such that the concentrations  $a_0$  and  $a_1$  are held constant at 100 and 0.1 respectively. Conceptually,  $A_1$  flows into the system, then undergoes a series of reactions until it is converted into  $A_2$ , at which point it is removed. Boundary conditions of this type could be achieved experimentally

Figure 3: Time series of the concentrations in the model when  $n = 6$  and  $n = 7$ . In both cases there is a period of exponential growth from  $t = 0$  to about  $t = 2.0$ , indicating autocatalysis. This is followed by gradual saturation.

using membrane permeable only to small molecules.

Figure 3 shows the dynamics of this system when  $n = 6$  and  $n = 7$ . In both cases there is a period of exponential growth followed by a period of saturation. Exponential growth is a key experimental sign of autocatalysis. (With  $n \leq 5$  this effect does not occur.)

Figure 4 shows the reaction networks that arise once these systems have reached a steady state. (We were unable to find more than one attractor in these particular systems, although the existence of others cannot be ruled out.) The recycling structure of these networks can be seen as a response to the flux of Gibbs energy across the system's boundary, in accordance with Morowitz' (1966) cycling theorem. It is for this reason that we believe including thermodynamically realistic kinetics in such models is important for understanding the origins of autocatalytic cycles.

In both cases the mechanism behind the exponential growth is an autocatalytic cycle that produces two molecules of an intermediate for every molecule present initially; this exponential growth is countered by decay reactions once the concentrations become high. However, the two systems use different autocatalytic cycles. This is possible because the direction in which reactions occur is determined by the differences in the reactants' chemical potentials, and these depend upon the system's dynamics.

As  $n$  is increased further, more catalytic and autocatalytic cycles emerge (results not shown). However, it can be seen from Figure 3 that the concentrations of longer polymers are much higher than those of short ones; this trend continues as  $n$  is increased, leading to unrealistic results as  $n$  becomes large, since in reality a system composed mostly of long polymers will become viscous or solid, preventing further reactions by suppressing mixing.

However, this issue can be resolved by choosing different values for the parameters, so that shorter rather than longer ones are thermodynamically favoured. In addition to doing this we set  $n$  large enough that the longest polymer only

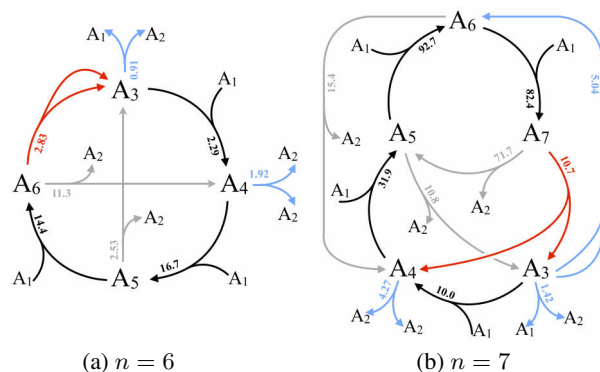

Figure 4: The reaction networks that form when  $n = 6$  and  $n = 7$ , with  $p = 1$  and the concentrations of  $A_1$  and  $A_2$  held constant. Propagating reactions are shown in black or grey, branching reactions in red, and terminating reactions in blue. Numbers represent the rate at which each reaction occurs once a steady state is reached, in multiples of  $10^{-3}$  concentration units per time unit. The set of allowed reactions is predetermined, but the direction in which they proceed depends on the system's dynamics. Both networks contain several catalytic cycles, coupled to an autocatalytic cycle (highlighted in black). The reaction  $A_6 \rightarrow 2A_3$  is the key branching step when  $n = 6$ , but when  $n = 7$  it runs in the opposite direction, becoming a depleting reaction.

ever exists at a low concentration. The parameters we use are  $K = 100$ ,  $p = 0.2$  and  $n = 40$ . When such a system is driven toward a steady state, it produces very complex networks that are difficult to analyse. Andersen et al.'s (2012) algorithm could be used to detect autocatalytic subnetworks, but it cannot tell us how viable they are. Because of this, instead of driving the system we simply initialise it in a state with a high Gibbs energy and observe its return to equilibrium. This allows us to detect autocatalysis by observing exponential growth in the kinetics. We use the initial conditions  $a_1 = 1000.0$ , and  $a_i = K^{1-i}$  for  $i > 1$ . This can be interpreted as a system that was initially in equilibrium, to which a large quantity of monomers has just been added.

Figure 5 shows the results of this simulation. We numerically integrated the dynamics of 50 randomly generated networks for 3 time units each. In 32 out of the 50 cases, no reactions occurred and the system remained in its initial state. In 14 out of the remaining 18 cases, there was at least one period of time in which a species' concentration increased with  $d^2a_i/dt^2 > 0$  and  $da_i/dt > 0.01$ . Such "accelerating" growth is an indication that there is a viable autocatalytic network within the system.

The behaviour of the system is quite sensitive to the choices of parameters, but the phenomenon of exponential growth appears to be fairly robust. Quantifying this is a task for future work.

Figure 5: (a) An example of the dynamics when  $n = 40$ ,  $p = 0.2$  and the system is closed but initially out of equilibrium. In this case the reaction  $2A_1 \rightleftharpoons A_2$  rapidly goes to equilibrium and the system stays in this state for a while before a complex autocatalytic network arises and rapidly brings the system near to thermal equilibrium. (b) Superimposed results from 50 networks, showing the change in Gibbs energy over time. The initial conditions are identical for each network and have a Gibbs energy of about 6900, whereas the equilibrium state has a Gibbs energy of about 4300. The lines are coloured red when at least one species in the system is increasing with a positive second time derivative, indicating the presence of a viable autocatalytic network. The systems typically approach equilibrium more rapidly when an autocatalytic network is operating.

## Discussion and Future Work

We have presented a model that couples a simple abstract chemistry with thermodynamically realistic kinetics, in order to show that autocatalysis via branching chain reactions can occur even in very simple chemical systems. The origins of life are often thought of in terms of a “self-replicating molecule” which, as Figure 2b shows, can be thought of as a small autocatalytic cycle composed of reactions between complex molecules. Our results suggest that it may be much easier to achieve the opposite: a large autocatalytic network composed of simple molecules.

An important property of our model is that both forward and reverse reactions are included, subject to thermodynamically realistic kinetics. As a result of this we can observe that an externally introduced source of energy drives cycling behaviour (Morowitz, 1966), and this recycling leads to autocatalytic kinetics (King, 1982). We therefore believe that adding reverse reactions and thermodynamic constraints to “abstract chemistry” models along the lines of (Fontana and Buss, 1994) could shed light on the process of novelty generation in general, as well as the origins of life in particular.

The main components of our model are (i) a system that is at least partially closed to matter flow, in which both synthesis and decomposition reactions can occur; and (ii) an energetic driving force, which causes some reactions to be

favoured over others. The simplicity of our model suggests that such conditions are essentially all that is required for autocatalytic networks to form. This makes it much more plausible that autocatalytic chemical systems could emerge on the early Earth, and the simplicity of the conditions makes the idea amenable to experimental testing in real chemistry.

It has been shown that Kauffman’s autocatalytic sets are capable of evolution by natural selection, even without the existence of specific information-carrying molecules (Vasas et al., 2012). Our hope is that something similar will be true of autocatalytic systems that occur via chain reactions rather than single-step enzyme-like catalysis. If this is the case then we may suggest that life did not start with the citric acid cycle but with a different autocatalytic system, perhaps composed of simpler molecules, but forming a much more intricate network of reactions. The catalysts required to produce the molecules of modern life via the reductive citric acid cycle could then have been arrived at by natural selection acting on the original autocatalytic system.

However, the models we have presented here seem not to exhibit the large number of attractors that would enable heredity in such a way. We must therefore discuss what additional conditions might need to be met in order for an evolvable system to arise.

## Constraints on the Reaction Network

Our model obeys constraints imposed by mass conservation and the laws of thermodynamics, but beyond this we choose the permitted reactions at random. As we have seen, this results in autocatalytic networks that tend to include almost every possible species as part of their network. In order for the system to exhibit a large number attractors there would need to be multiple possible autocatalytic networks capable of out-competing each other.

Real chemical reaction networks are not random but are determined by the physics of molecular interactions. This imposes a number of constraints both on the topology of chemical reaction networks and on their kinetics, and such constraints might help to “partition” the network into multiple potential autocatalytic sub-networks. Perhaps the most obvious such constraint is imposed by stoichiometry: chemical reactions must conserve not only mass but also the number of nuclei of each chemical element, as well as electrons. Our system recycles monomers, but in biology (particularly at the ecosystem level) the recycling of specific nutrients such as nitrogen and phosphorous plays an important organising role. We therefore suspect that adding multiple conservation laws to our model will enable a richer range of behaviours than it currently exhibits. (However, this would greatly increase the number of possible molecular species in the model, requiring a change in modelling methodology from the simple ode integration that we have used here.)

Another important set of constraints are given by the shapes of molecules and the ways in which they interact

electromagnetically. This gives reaction networks the important property that similar molecules can undergo similar reactions. Modelling the relationship between the form of molecules and the resulting reaction network is of course rather difficult, but perhaps something like the approach of Fontana and Buss (1994), combined with the thermodynamic realism of the present model, would be a useful tool to investigate this question.

Finally, the existence of phase changes can also put constraints on the reaction network. King (1982) argued that this could enhance the formation of viable autocatalytic cycles. Adding phase separation to our model would allow us to investigate this idea.

### **The Importance of Spatial Structure and Compartmentalisation**

In addition to phase separation, more complex spatial structuring may be important in going from simple to more complex autocatalytic networks. Many previous studies, including some by the present authors, have concluded that spatial self-organisation is important for avoiding “parasitic” side-reactions, i.e. sets of reactants that produce themselves autocatalytically, feeding not directly on the energy source but on the original autocatalyst (e.g. Boerlijst and Hogeweg, 1991; Froese et al., 2011, 2012, 2013). In (Froese et al., 2012; Virgo et al., 2013) we found that in a spatial context, parasitic reactions could become a positive benefit to the primary autocatalytic system, leading to evolvability. We expect that embedding a system along the lines of the present model in a spatial context will lead to richer dynamics.

Many hypotheses about the origins of life require “compartmentalisation”, the formation of a lipid vesicle, or similar small compartment, in which reactions take place. One reason for this arises from energetics: for complex biological polymers such as peptides to form, the monomers must be present in sufficient concentration, and since large monomers like amino acids or RNA bases are difficult to produce in such concentrations, a membrane is required in order to prevent them from diffusing into the environment.

With simpler molecules the energetics of polymerisation are less constrained, and simple monomers could more easily be produced abiotically. Compartmentalisation is therefore less critical for the kind of prebiotic system we consider in this paper, and one can therefore imagine such phenomena occurring in a relatively dilute “prebiotic soup”, or more accurately, a prebiotic flow reactor.

A second reason to require compartmentalisation is simply that there must be a population of multiple individuals in order for natural selection to occur. We suggest that simple spatial separation could have played this role originally, in a manner outlined in (Virgo, 2011; Froese et al., 2012), only later to be replaced by membrane-bound cell structures.

If autocatalysis can occur in solution, and if the autocatalytic network also produces lipid-like molecules, then

membrane-bound protocells may be able to form spontaneously (Ono and Ikegami, 2000; Madina et al., 2003). This neatly solves the chicken-and-egg problem of how membrane-bound autocatalysis could first have arisen.

### **Towards Empirical Verification**

In our model, autocatalysis via branching chain reactions emerges in a system that contains only simple synthesis and decomposition reactions, together with a supply of free energy. This idea should be relatively easy to demonstrate experimentally. Previous experiments relevant to the origins of life, such as the Miller-Urey experiment Miller (1953) or the polymerisation of hydrogen cyanide (HCN) (see, e.g., Minard et al., 1998) have focused on the production of organic molecules through polymerisation. Both of these experiments produce a diverse mixture of products, including amino acids; however, these products form into a black, sticky “tar” called tholin that seems unlikely to self-organise into anything like a biological metabolism, despite the fact that tholin itself is thermodynamically unstable and can be used as an energy source by several common species of bacteria (Stoker et al., 1990).

Our results suggest that autocatalytic cycles may emerge in such experiments if the conditions are changed so that breakdown of polymers via hydrolysis or oxidation can occur simultaneously with the polymerisation, at a comparable rate. Since polymer molecules are continually built up and broken down, we would expect those that can produce themselves autocatalytically to persist at the expense of those that cannot. The kinetics and energetics of both polymerisation and depolymerisation are sensitive to environmental factors such as temperature, pH, monomer concentration and the presence of surfaces and inorganic catalysts. Achieving autocatalysis should simply be a case of setting the appropriate conditions for the reaction. We are currently working on demonstrating this in an HCN polymerisation experiment.

The challenge in such an experiment is in demonstrating that an autocatalytic cycle has indeed emerged. The sheer number of products means that the resulting mixture tends to have a continuous mass spectrum, making it difficult to identify which species are present. However, evidence for autocatalytic kinetics would be given by sudden changes in the mass spectrum, even if one cannot readily identify the species responsible.

### **The Prebiotic Ecosystem**

Above we have mentioned several phenomena, such as nutrient cycling and parasitism, that one would normally associate with physical ecology than purely chemical systems. It is worth drawing an explicit conclusion from this: we believe that prebiotic systems should be thought of as resembling ecosystems, complete with food chains, nutrient cycling, energetic restrictions and all the rest — everything except for clearly differentiated living cells, which arose later.

We know that the early Earth was a very active world, with sources of chemical free energy from UV photochemistry in the atmosphere, shockwaves from asteroid impacts, radioactivity, lightning, volcanoes and geochemistry (Deamer and Weber, 2010), and matter cycling due to plate tectonics and the water cycle. In such a context, it is easy to imagine that such prebiotic ecosystems could have been a global phenomenon, leading to primordial equivalents of today's biogeochemical cycling of nitrogen, phosphorous and carbon. From this point of view a homeostatically self-regulating Earth system should be seen not as a *consequence* of the biosphere (Lovelock, 1987), but rather as the context in which it first arose.

## Conclusion

We have set out to explain how autocatalysis could have emerged on the early Earth, before the existence of enzyme-like catalysts. We have shown, using a simple model, that autocatalytic cycles can emerge in chemical systems with only synthesis and decomposition reactions, without requiring the molecules to have special catalytic properties. The resulting autocatalytic networks solve the problem of specificity not by being small and simple but by being large and complicated. We conclude that the earliest origins of life may have lain not in a "minimal" autocatalytic system but in a "maximal" one.

The conditions required for this to occur are simple enough that we hope it can be demonstrated in wet chemistry experiments, and we have discussed how this could be achieved. Finally, based on our results, we have argued that the prebiotic Earth should be seen not as a soup but as an ecosystem.

## Introduction

Modern conventional computers are programmable, predictable and relatively easy to understand and engineered—at least compared to most complex non-linear systems. These properties are the result of various dynamical constraints that are universal to conventional computers, such as the clock mechanism that synchronises the update of logic gates and other components; the ubiquitous discretization steps (where continuous values are discretized into binary 1s and 0s); and the almost complete isolation of internal processes of computers from the environment of the computer. We are investigating an alternative computational medium composed of signalling synthetic protocells to explore the implications of relaxing some of these dynamical constraints that are typical of conventional computers. Is it possible to build useful and/or programmable computers out of unconventional media such as protocells that do not have a synchronizing clock? Or that do not employ a conventional representation of 0s and 1s? Or that are less decoupled from their environment?

The protocells that we are investigating are aqueous droplets suspended in oil. Each droplet contains the reagents for the Belousov-Zhabotinsky (BZ) oscillating chemical reaction (Zhabotinsky, 2007), resulting in self-exciting dynamical units that, when in contact with each other, are capable of propagating signals similar in some respects to signal transduction in biological neurons. Networks of these signalling protocells are therefore a kind of *wet* artificial neural network, sharing more in common with biological nervous tissue than conventional computer electronics.

It is envisaged that in the future more advanced protocells will be employed to make self-organising computers, or computers that can operate within the human body. But first it is necessary to develop a better understanding of how complex non-linear systems can be harnessed to accomplish useful or “minimally-cognitive” tasks (Beer, 2003) such as categorical perception, boolean logic, and dynamical control.

Moreover, by learning how to construct or assemble networks of complex non-linear units like the BZ-protocells

we also gain insight into how other complex and non-linear “computational” media (such as nervous tissue) can conduct, modify and modulate signals and information, and how it can play an important role in the sensorimotor loops of a situated and embodied agent (Stewart et al., 2011). This bottom-up approach to the construction of alternative computational media is an important complement to the more widespread top-down neuroscience where biological neural networks are slowly being reverse engineered.

With these long and medium-term goals in mind, we have set out to (i) design functional collections of signalling protocells (comparable to the logic gates of conventional computing) that could be combined to produce more complex networks, (ii) identify effective signal encoding(s) that facilitate the transmission and manipulation of the signal by protocell networks, and (iii) identify design techniques and methodologies for creating functional signalling protocell networks out of complex non-linear media. To accomplish these goals, we are taking a three pronged approach involving *in vitro* experimentation, simulation and modelling to investigate the dynamical properties of the protocells and networks thereof; and experimental computer-aided design and machine-learning techniques to partially automate the development of functional protocell networks. We now briefly summarize our published results, before describing our current efforts.

## Summary of published research

To elucidate the experimental foundations of working with wet chemical computers on microfluidic chips (King et al., 2012), the NeuNeu project consortium ([www.neu-n.eu](http://www.neu-n.eu)) has conducted various research projects involving simulation, modelling and experimentation. One branch of this research involves the investigation of droplet networks, where the droplets are assumed to be small enough that internal spatial dynamics can be ignored. In this vein, the computing potential of two-droplet systems has been demonstrated in experiment and simulation (Szymanski et al., 2011) and differential equation models have been identified that allow us to accurately describe droplet dynamics and interactions (Szy-

manski et al., 2011). More abstract simulation models have also been developed to make possible faster and larger-scale simulations (Gruenert et al., 2013), allowing us to analyse higher-level design principles and questions pertaining to system architecture, such as possible benefits of moving beyond naive or simple signal encodings (e. g. high firing-rate = 1, and low firing-rate = 0) to explore various alternatives (Gruenert et al., 2012).

In a parallel branch of simulation and experimental work, our collaborators have been investigating more spatial forms of computing, involving larger reservoirs containing sub-excitable BZ medium. In these conditions, isolated spatial propagating waves can form, combine and interfere in spatial and geometrical ways to accomplish computation-like tasks, such as logic gates (Holley et al., 2011; Adamatzky et al., 2012).

### Ongoing research

#### Information measures for analysing and guiding the artificial evolution of unconventional computational media.

Following information theory (Shannon and Weaver, 1948) and information dynamics measures (Lizier, 2013) in cellular automata and in neural networks (Vicente et al., 2011), which help to identify information propagation, storage and modification systems, we are developing analysis tools for understanding the information flows of experimental and simulated droplet systems. These tools are intended to aid in the tracking and understanding of the flow of information through unconventional computational media, in a way that is largely independent of the encoding of the information and to thereby facilitate the search for complex and potentially useful system behaviours in random or evolved droplet networks, which are inherently less modular and decomposable than conventional engineered computational systems. We are also exploring the use of information theoretical measurements to constrain the design of functional networks. By identifying necessary changes in the state of information at different stages of computation, we believe it may be possible to guide machine-learning algorithms to more effectively design functional networks.

#### Defining computational-unit fitness implicitly using tautological closed loops.

To facilitate the artificial evolution of Basic Composable Units (“BCUs” – c.f. logic gates) for unconventional computational media, we are developing a novel technique in which optimal BCU behaviour is defined not explicitly (“given this input, the unit should produce that output”), but implicitly, through its influence on network properties in a closed network consisting of multiple instances of the unit. The network is designed in such a way that only if the units are performing the desired task (e. g. acting as a NAND gate), will certain network properties hold (e. g. dynamics at

two points in the network should be similar to each other and different to a third point), and machine-learning techniques tune the BCU properties to maximise these network properties. In this way, we implicitly describe the desired behaviour of the units without overly constraining their design, allowing the artificial evolution to concurrently design the BCUs and the encoding of the signal that they operate upon.

### Abstract

Recent research on the notion of altruism in terrestrial life has focused on certain altruistic behaviors, which are regarded as beneficial to animal life, especially with respect to individual animal species. Such findings throw light on individual-oriented mechanisms and their evolution in helping to clarify so-called intentional interactions between individuals based on discrimination of other individuals and remembered information as advanced by developments in biological information processing, ranging from molecular recognition to activation of the neural system. In 2006, Nowak classified these mechanisms into five types. In the current study, we have zeroed in on the process of autolysis universally observed in all terrestrial lives, as characterized by genetically programmed death accompanied by altruistic self-decomposition, whose model we call the “programmed self-decomposition model (PSD Model)”. In our view, altruistic phenomena target no specific individuals yet prove beneficial to the ecosystem, in part and as a whole. Using our PSD Model we ran evolutionary simulations of altruistic phenomena in the SIVA Series, which is an artificial life system designed to resemble a terrestrial ecosystem, and one that excludes both discrimination of individuals and interactions between individuals. In our simulations no individual-oriented evolutionary mechanism was observable while the ecosystem-oriented mechanism positively contributed to the evolution of the altruistic gene. Our research has thus sought to determine factors that promote superior evolutionary characteristics of altruistic phenomena in a terrestrial ecosystem model. The current study argues that the high heterogeneity and complexity of a terrestrial environment and the eternality of evolutionary time play an important role in the selective process of programmed death in the terrestrial ecosystem, which is accompanied by altruistic self-decomposition. Based on the above findings, we investigated the inseparable relationship existing between a terrestrial ecosystem and the altruistic gene.

### Introduction

We previously modeled autonomous death that comprises a universal attribute of terrestrial life, as programmed self-decomposition (PSD) (Oohashi et al. 1987, 2009). Our research centers on a series of studies that delve into the existence of autonomous death through experiments in the field of molecular cell biology using existing living organisms as subjects; concurrently, in carrying out evolutionary simulations of Artificial Life (ALife), we raise the possibility

that mortal organisms having autonomous death are superior to immortal organisms (Oohashi et al. 1987, 1999, 2001, 2009, 2011, 2014; Maekawa et al. 2011). The essence of our PSD model zeroes in on the process of autolysis (Odum 1971), which is universally observed in terrestrial lives including unicellular organisms, as phenomena with respect to recycling of autonomous material in a terrestrial ecosystem. Conventionally autolysis has been regarded as deregulated, natural disintegration with increasing entropy. We have redefined autolysis as a type of autonomous, altruistic phenomenon beneficial to an ecosystem, in part or as a whole. We thus regard autolysis as an active biochemical process built into cellular genetic programming by which a cell consumes its own metabolic energy. In view of this autolytic process, we posit that life individuals autonomously decompose themselves into components; in other words, cells hydrolyze biological polymers into biological monomers so that the materials they consume and the spaces where they exist can be optimally reutilized by all other life individuals, including adversaries and competitors, and, by means of that event, can thereby return to the environment and thus contribute to the restoration of the entire ecosystem.

Recent research on the concept of altruism in terrestrial life has focused on certain altruistic behaviors regarded as beneficial to animal life, especially with respect to individual animal species (Haldane 1932; Hamilton 1963; Price 1970). Based on these many previous researches, Martin A. Nowak has provided a useful framework that classifies the mechanisms of evolution of cooperation under five types (Nowak 2005, 2006, 2011, 2012). His rules quite adequately account for altruistic phenomena that targets only specific individuals or groups. Nowak’s five rules for these mechanisms require, as prerequisite functions, discrimination of other individuals and reference to remembered information, as advanced by developments in biological information processing, ranging from molecular recognition to activation of the neural system. Such altruistic behavior is realized by the individual-oriented mechanisms whose actual property is the intentional interaction between individuals based on such rules. The terrestrial lives that Nowak’s framework of altruistic behavior encompasses are limited to relatively evolved animals that deploy biological control systems that enable the discrimination between individuals and the remembering of an individual’s experience (Oohashi et al.

2014), at least as chemical messengers, and, ideally, a central nervous system sufficiently robust for formation intention.

We have redefined an altruistic phenomenon as being a phenomenon by which a life individual renders certain biological benefits to a part of the ecosystem including individuals as well as to the ecosystem as a whole, regardless of any biological benefit for or disadvantage to itself (Oohashi et al. 2011, 2014). In our view, the recipient of a contribution should not only be limited to a specific individual or a group of individuals; but rather, include the ecosystem, in part or as a whole. Consequently, we put forth the programmed self-decomposition model as an ecosystem-oriented altruistic phenomenon that emerges even for very primitive life individuals equipped with only the fundamental principle of terrestrial life, namely, self-reproduction and self-decomposition regulated solely by a genetic program, and without any functionality by which to discriminate between individuals (Oohashi et al. 2014). Considering that the essential quality of the PSD consists of autolysis and that organelles (lysosome) executing PSD exist in every eukaryote cell, it would be possible for PSD to serve as a mechanism universally existing in terrestrial lives, and for it to exist as a universal basic mechanism for all eukaryotes, including animals that produce the individual-oriented altruistic behavior proposed by Nowak.

Based on the conceptual clarification of altruistic phenomena, we constructed a simulator system SIVA Series equipped with primitive artificial life in an ecosystem designed to resemble a terrestrial ecosystem, and one that excludes both discrimination of individuals and interactions between individuals. Through a series of simulation studies, we showed many conditions whereby evolutionary adaptation is promoted by means of altruism even in extremely primitive lives equipped only with the basic principle of terrestrial life, that is, the self-reproduction and self-decomposition regulated solely by a genetic program (Oohashi et al. 1987, 1999, 2001, 2009, 2011, 2014; Maekawa et al. 2011). Especially noteworthy is our finding that the gene of altruistic death accompanied by programmed self-decomposition can be acquired through the evolution of immortal lives, and the lives that acquire the gene of altruistic death sometimes are overwhelmingly superior to immortal lives (Oohashi et al. 2014, Maekawa et al. 2011). Accordingly, we regard altruistic death accompanied by programmed self-decomposition as a sophisticated survival strategy acquired as the fruit of evolution. We thus categorize lives that have completed this

evolution as altruistic mortal lives and more primitive lives that have yet to complete such evolution as non-altruistic immortal lives.

This study examined the possible reasons why altruistic phenomena of programmed self-decomposition brought forth evolutionary superiority in terrestrial ecosystem models. We therefore hypothesized that the high heterogeneity and complexity of terrestrial environments and the eternity of evolutionary time of a terrestrial ecosystem played important roles in the selective process of programmed death, which is accompanied by altruistic self-decomposition in terrestrial ecosystems. In our experimental models using artificial lives, we carried out experiments that tested our hypothesis and obtained positive results. Here we describe the results.

## Methods

### 1) Design of the SIVA simulator and its virtual environment

In the present study, we again used SIVA-T05 as an evolution simulator. Its construction and functions are the same as those utilized in a previous report (Oohashi et al. 2009).

To simulate the characteristics of a terrestrial environment using a limited amount of materials distributed in a finite space, the virtual space of SIVA-T05 is designed to be a two-dimensional lattice consisting of  $16 \times 16$  (= 256) spatial blocks. A single spatial block is defined as  $8 \times 8$  (= 64) pixels for habitation points. One habitation point is occupied by one virtual life individual (VLI) and vice versa (Figure 1a). Environmental conditions can be independently defined for each spatial block and those of the 64 habitation points in the same spatial block are configured to always be homogeneous. Since all VLIs in one spatial block share identical environmental conditions, the population of VLIs in that block significantly affects local conditions.

In the present study, the temperature gradient and the initial distribution of four kinds of virtual inorganic biomaterials making up the VLIs were set to be heterogeneous or homogenous across the whole ecosystem according to experimental conditions (see next section). No substances other than virtual inorganic biomaterials existed in the initial environment.

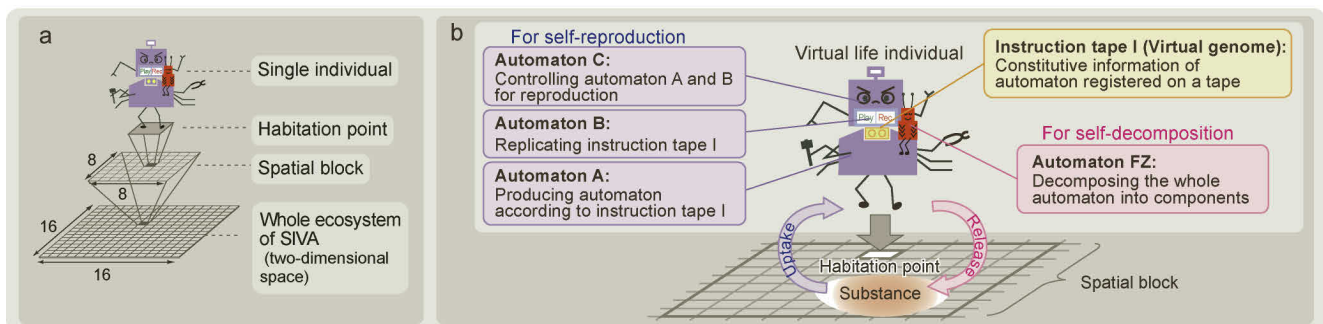

Figure 1. Environmental design and life activities of virtual life individuals (VLIs) of the virtual ecosystem SIVA-T05. a) Environmental design. b) Relationship between life activities of virtual life individuals (VLIs) and the environment.

## 2) Structure and behavior of artificial life

**Structure of a virtual life individual.** As in the previous report (Oohashi et al. 2009), we designed a virtual life individual (VLI) based on Oohashi's self-reproductive, self-decomposable (SRSD) automaton model (Figure 1b) that took von Neumann's self-reproductive automaton model (Von Neumann 1951) as its prototype (Figure 2). Oohashi's automaton G is described as  $G = D + FZ + I_{D+FZ}$ , where  $D = A + B + C$ . Here, automaton A produces automata according to instructions on data tape I (that is, a virtual genome). Automaton B reads and replicates data tape I. Automaton C sets the copy of data tape I replicated by automaton B into new automata produced by automaton A and separates these as automaton D. Automaton FZ, which is a modular subsystem plugged into automaton D, decomposes the whole automaton G into components suitable for reutilization when automaton G encounters serious environmental conditions in which it is unable to live or has reached the end of its life span. Data tape  $I_{D+FZ}$  carries an instruction describing automaton D + FZ. Thus, automaton G, which corresponds to  $D + FZ + I_{D+FZ}$ , can reproduce an identical automaton G as well as decompose itself.

We designed artificial life based on AChem (Dittrich et al. 2001; Suzuki 2004) so as to realize the above-mentioned

logical behaviors and, as faithfully as possible, to reflect the principles of terrestrial life and its subsequent reproduction. We constructed a VLI from four classes of virtual biomolecules: virtual inorganic biomaterials (VI), that are four kinds of substances distributed in the environment; virtual organic biomaterials (VO); virtual biological monomers (VM); and, virtual biological polymers (VP). Any molecules in the latter three classes consist of combinations of the four kinds of VI. A virtual genome in the VP class consists of virtual nucleotides belonging to the VM class. The virtual protein in the VP class is produced according to a sequence of virtual nucleotides that determines the primary sequence of virtual amino acids belonging to the VM class (Oohashi et al. 2009). We developed a SIVA language that actualizes virtual life activities by recognizing the sequence of the virtual amino acids contained in the virtual protein as coded program sentences then executes the specific life activity. According to given conditions, this SIVA language reproduces, divides, and decomposes a VLI.

Each VLI expresses its life activities by executing all sentences satisfying their execution conditions in the VLI during one Time Count (TC), the unit of virtual time in SIVA-T05. The order for a VLI in the virtual ecosystem to express its life activities within one TC is randomly determined at every TC. It takes at least 5 TCs for a newborn individual to reproduce itself in our current simulation experiments.

Figure 2. Von Neumann's self-reproductive automaton and Oohashi's self-reproductive, self-decomposable automaton.

(A) Von Neumann's self-reproductive automaton model. This is an immortal type model without an autonomous mechanism for the restoration of the environment to its original state. (B) Oohashi's self-reproductive, self-decomposable (SRSD) automaton model. This model uses von Neumann's self-reproductive automaton model as its prototype. It has a programmed mechanism contributing to the restoration of the environment to its original state through autonomous individual death with self-decomposition, which is an essential feature of terrestrial life. Two activation modes are defined for the self-decomposition automaton FZ. The first one is activated by a signal input from outside, indicating unconformity between the life and its habitation environment. The second mode constitutes the end of the life span.

Therefore, we use “passage duration” as a virtual time unit, which corresponds to the value of TC divided by 5 (Oohashi et al. 2009).

**Behavior of virtual life individuals.** A VLI executes its life activities by consuming materials from the virtual environment (Oohashi et al. 2009). Activities of each VLI are so designed as to depend on the amount of material available as well as the temperature in the inhabited spatial block. Namely, optimum environmental conditions are defined for each VLI a priori. Activities of a VLI decrease when environmental conditions of the habitation point move away from VLI optimum points. A VLI cannot express its life activities when environmental conditions markedly deviate from the optimum, and, in the case of a mortal organism, it decomposes itself just as it does when it has lived out its life span. Materials released by the decomposition of a VLI are restored to the environment and become utilizable by other individuals as well as the space that were occupied by the VLI.

When VLIs reproduce, point mutation can occur at a predefined probability during replication of the virtual genome. Mutations may alter the optimum environmental conditions for a VLI such as temperature and the composition of the VIs. In addition, VLIs which can use only VI for self-reproduction, which requires a greater amount of energy, can evolutionarily become those which can also use VM, which requires smaller amount of energy. In other words, the evolution of the material uptake function is also installed. These mutations enable the VLI to live in an environment where it originally could not live. That is to say, evolutionary adaptation to the environment can occur.

### 3) Experimental setting

To evaluate the hypothesis that the high heterogeneity of terrestrial environments and the eternity of the evolutionary time of a terrestrial ecosystem played an important role in the selective process of programmed death, which is accompanied by altruistic self-decomposition of the terrestrial ecosystem, we employed artificial life in three experimental conditions in which different initial distributions of VIs and temperature were employed as shown in Figure 3: experimental condition A: initial distribution of both VIs and temperature optimal level for VLIs was homogenous throughout the whole environment; experimental condition B: initial distribution of

VLIs was homogenous whereas initial distribution of temperature was heterogeneous; and, experimental condition C: initial distributions of both VIs and temperature were heterogeneous. Under each experimental condition, we seeded an altruistic mortal VLI and a non-altruistic immortal VLI in spatial blocks in the midst of the simulation space whose environmental conditions were most suitable for these VLIs to start simulations of their reproduction and evolution. We conducted 100 simulations of 800 passage durations with a mutation rate of 0.005 and observed changes in the size of habitation area and number of VLIs. Since mutation occurs at each reproduction according to the configured mutation rate under the current experimental conditions, we calculate the approximate magnitude of the mutations that occur during the simulation by means of the total number of reproductions. Therefore, we aggregated the number of reproductions for both mortal VLIs and immortal VLIs to compile the cumulative mutation index.

## Results

Figure 4 shows the typical transition pattern of distribution of VLIs, their number, and the cumulative mutation index of more than 800 passage durations for each of three conditions set according to the level of environmental heterogeneity. Table 1 shows the ratio of survival of VLIs up to either the 400<sup>th</sup> passage duration or the 800<sup>th</sup> passage duration, average and standard deviation ratio of number of mortal VLIs to that of immortal VLIs at the 400<sup>th</sup> and at the 800<sup>th</sup> passage duration when immortal VLIs survived, and the cumulative mutation index for both mortal VLIs and immortal VLIs at the 800<sup>th</sup> passage duration of a typical example as seen in Figure 4.

Under Condition A, when both substances and temperature were homogeneous, immortal VLIs were greater in number with continued reproduction but after the 200<sup>th</sup> passage duration, the VLIs filled the entire simulation space and entered a stable phase. On the other hand, mortal VLIs reproduced themselves until the 10<sup>th</sup> passage duration after the onset of simulation. However, when passage duration exceeded 10, reproduction of mortal VLIs stagnated that reduced their number so that there were twice as many immortal VLIs as mortal VLIs at the 15<sup>th</sup> passage duration. After 20 passage durations, the number of mortal VLIs once again increased at a rate of increase similar to that of immortal

Figure 3. Three experimental conditions showing initial distribution pattern of virtual inorganic biomaterials (VIs) and temperature.

A) VIs: homogeneous, Temperature: homogeneous. B) VIs: homogeneous, Temperature: heterogeneous. C) VIs: heterogeneous, Temperature: heterogeneous.

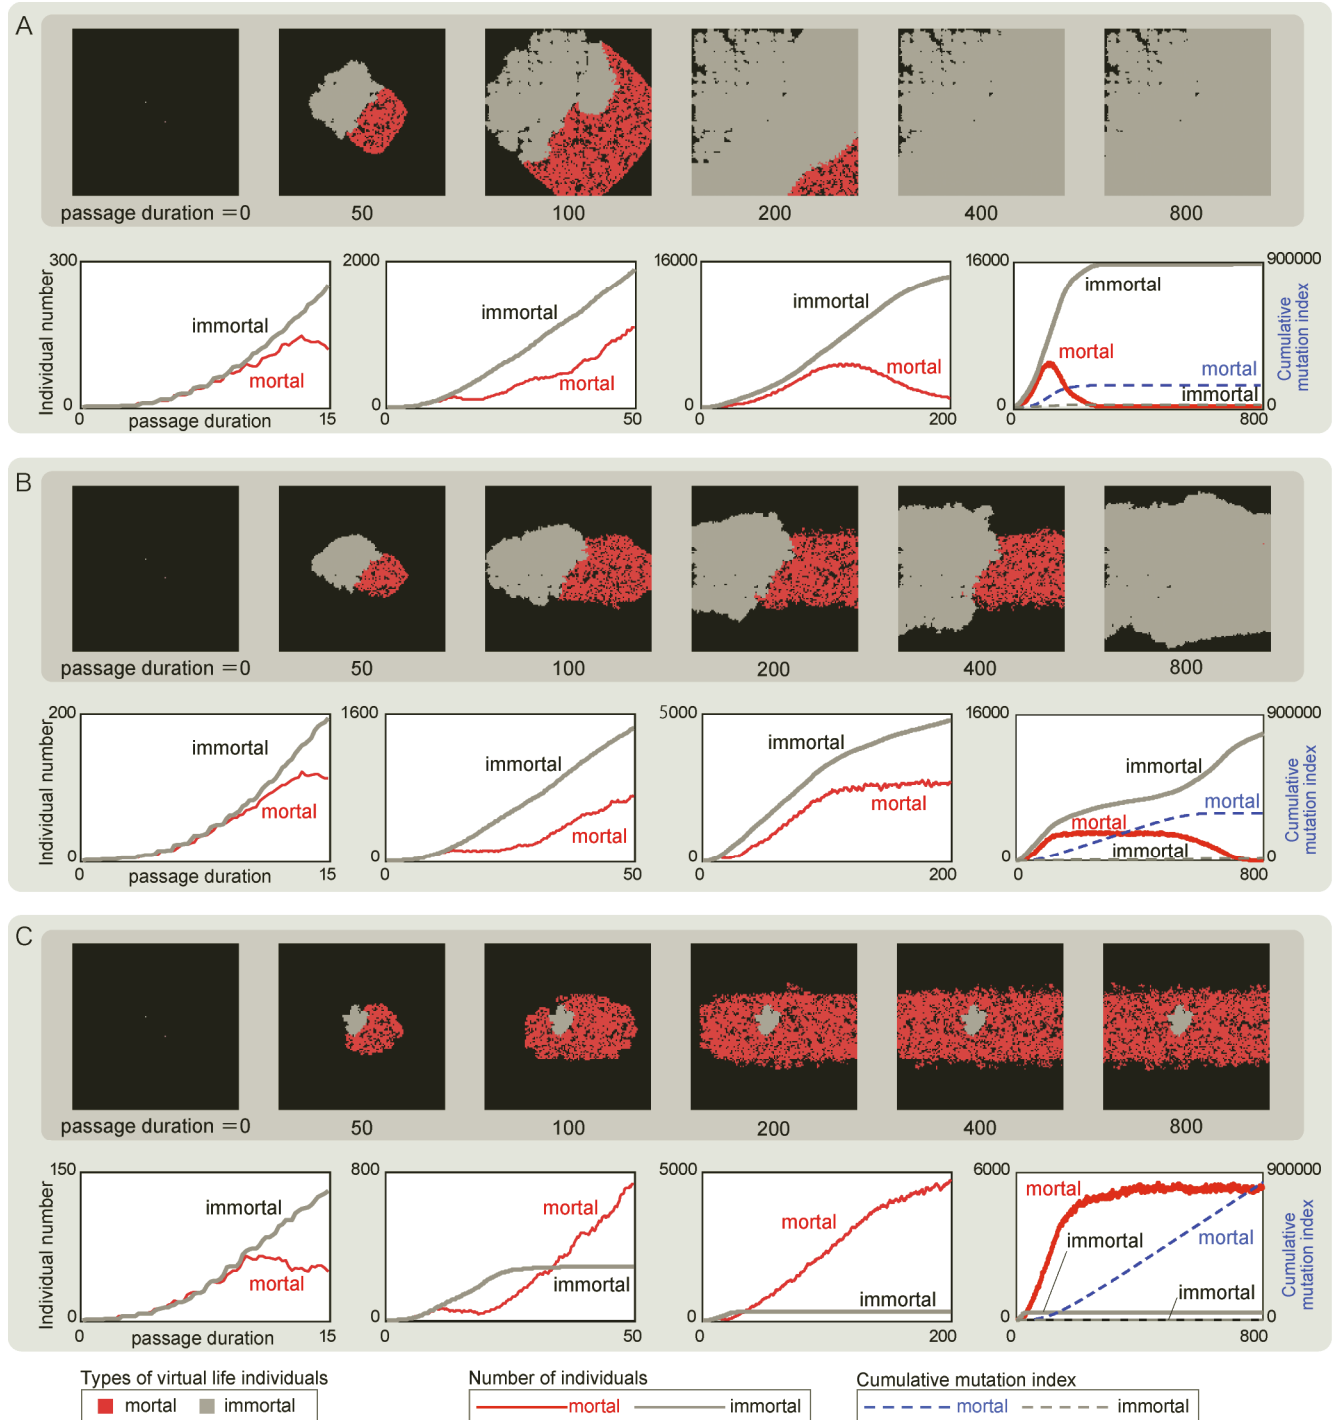

Figure 4. Altruistic gene became more superior as heterogeneity and complexity of the environment became greater. Successive changes in individual distribution (upper panels), the number of individuals (solid lines in lower panels), and the cumulative mutation index (dotted lines in the lower right panel) of mortal and immortal virtual life individuals (VLIs) simulated under each experimental condition: A) VIs: homogeneous, Temperature: homogeneous. B) VIs: homogeneous, Temperature: heterogeneous. C) VIs: heterogeneous, Temperature: heterogeneous.

Table 1: The superiority of the mortal VLIs led by the increase in heterogeneity and complexity in environmental conditions.

Condition			400 <sup>th</sup> passage duration		800 <sup>th</sup> passage duration		Cumulative mutation index		
			Ratio of survival (mortal VLs)	Average and SD ratio of number (mortal VLs / immortal VLs)	Ratio of survival (mortal VLs)	Average and SD ratio of number (mortal VLs / immortal VLs)	Typical values	Ratio (mortal VLs / immortal VLs)	
Substance (VLs)	Temperature								
A	homo-geneous	homo-geneous	0%	0	0%	0	mortal immortal	133910 15910	8.4
B	homo-geneous	hetero-geneous	8%	0.19±0.17	0%	0	mortal immortal	294747 13100	22
C	hetero-geneous	hetero-geneous	11%	18±2.1	11%	18±2.0	mortal immortal	840945 291	2890

VLIs. However, mortal VLIs increased until the 120<sup>th</sup> passage duration at which time they entered a reduction phase and died out after the 200<sup>th</sup> passage duration. Such a tendency was commonly observed in all of the 100 simulations executed, and mortal VLIs never survived until the 400<sup>th</sup> passage duration in any of the simulations. However, while the cumulative mutation index at the 800<sup>th</sup> passage duration of immortal VLIs was 15910, that of mortal VLIs reached 133910, 8.4 times that of the immortal VLIs. That finding shows that the magnitude of the cumulative mutation of mortal VLIs was much higher than that of immortal VLIs.

Under Condition B, when the temperature was heterogeneous while the initial distribution of substances was homogeneously distributed, immortal VLIs steadily increased and maintained a greater number than mortal VLIs. After reaching the 100<sup>th</sup> passage duration, the increase of the immortal VLIs slowed down then accelerated once again after the 600<sup>th</sup> passage duration in parallel with the decrease of mortal VLIs. In contrast, mortal VLIs started to reproduce but its number deceased at around the 10<sup>th</sup> passage duration. Then, at the 20<sup>th</sup> passage duration, mortal VLIs increased once again until reaching a plateau at around the 120<sup>th</sup> passage duration. At the same time, mortal VLIs remained constant in number and well-balanced with respect to reproduction and decomposition up to the 500<sup>th</sup> passage duration, and began to decrease at the 600<sup>th</sup> passage duration then dying out at the 800<sup>th</sup> passage duration. The ratio of survival rate of mortal VLIs at the 400<sup>th</sup> passage duration was 8%, but the number of mortal VLIs was, on average, 0.19 times that of immortal VLIs, which shows the absolute superiority of immortal VLIs to mortal ones in all trials. Furthermore, when we extended the evolutionary time of the simulation, mortal VLIs died out before reaching the 800<sup>th</sup> passage duration without exception. However, while the cumulative mutation index at the 800<sup>th</sup> passage duration of immortal VLIs was 13100, that of the mortal VLIs was 294747, which reached 22 times that of immortal VLIs. This finding shows that the magnitude of the cumulative mutation of mortal VLIs was even higher than that of immortal VLIs as compared to Condition A.

Under Condition C, when both temperature and initial distribution of substance were heterogeneous, immortal VLIs began reproduction in the same way as they did in Condition A and Condition B, but ceased reproduction after the 25<sup>th</sup>

passage duration, and were completely surpassed by mortal VLIs at the 30<sup>th</sup> passage duration. There was no notable change observed either in number or size of the area in which the immortal VLIs existed until they reached the 800<sup>th</sup> passage duration. On the other hand, mortal VLIs started to reproduce but its number deceased at around the 10<sup>th</sup> passage duration. Then, at the 20<sup>th</sup> passage duration, mortal VLIs increased once again and surpassed immortal VLIs in number at around the 30<sup>th</sup> passage duration, and continued to increase in number and size of the area in which they existed. At the 200<sup>th</sup> passage duration, the rate of increase declined but maintaining a stable balance between reproduction and decomposition up to the 800<sup>th</sup> passage duration. The number of trials in which mortal lives survived until the 400<sup>th</sup> passage duration increased from 8 to 11 out of 100 trials. They survived until the 800<sup>th</sup> passage duration. Both at the 400<sup>th</sup> and 800<sup>th</sup> passage duration, the number of mortal VLIs was, on average, 18 times greater than the number of immortal VLIs, which shows the overwhelming prosperity of the former. While the cumulative mutation index at the 800<sup>th</sup> passage duration of immortal VLIs was 291, that of mortal VLIs was 840945 (2890 times). This shows that the greatest magnitude of cumulative mutation was accumulated in mortal VLIs among the three environmental conditions with respect to heterogeneity. As shown above, when an environment is more heterogeneous and complex, the survival rate of mortal VLIs increases and the duration of survival becomes longer so that mortal VLIs overwhelm immortal VLIs even in the number of individuals in a heterogeneous and complex condition. The cumulative mutation was observed to be markedly greater for mortal VLIs than for immortal ones. Furthermore, it is noteworthy that even when mortal VLIs overwhelmed immortal ones in the final stage under a heterogeneous and complex experimental environment, immortal VLIs dominated mortal ones at the initial stage, up to the 30<sup>th</sup> passage duration without exception. This indicates that a certain length of time for evolution and prosperity is necessary before mortal VLIs can surpass and overwhelm immortal ones.

## Discussion

Using the SIVA Series, an artificial life system designed to resemble a terrestrial ecosystem that excludes both

discrimination of individuals and interactions between individuals, we examined factors that promote superior evolutionary characteristics of altruistic phenomena and a gene having altruistic properties.

Our results showed that immortal lives without altruistic properties are overwhelmingly more prosperous than altruistic mortal lives in a more homogeneous and simple artificial ecosystem with a shorter reproductive evolutionary time. On the other hand, the more heterogeneous and complex an environment having a longer reproductive evolutionary time is, the more dominant the altruistic mortal lives become over non-altruistic immortal lives. That is, when the substances necessary for reproduction of individual life and the temperature necessary for emergence of life-form activities were homogeneously distributed under simple environmental conditions at the initial stage, altruistic mortal lives were overwhelmed by non-altruistic immortal lives and never survived up to 400<sup>th</sup> passage duration in any of 100 trials. When, at the initial stage, the temperature was heterogeneous while the substances were homogeneously distributed as above, mortal lives survived up to the 400<sup>th</sup> passage duration in 8 out of 100 trials. Note, however, that the number of immortal lives exceeded the number of mortal lives at the 400<sup>th</sup> passage duration in all those 8 trials. Furthermore, when we extended the evolutionary time of the simulation, the mortal lives died out before reaching the 800<sup>th</sup> passage duration in all 8 trials.

On the other hand, when the temperature was heterogeneous and the initial distribution of substances necessary for living organisms was heterogeneously distributed to increase the complexity of environmental conditions, the number of trials in which mortal lives survived until the 400<sup>th</sup> passage duration increased from 8 to 11 out of 100 trials. Noteworthy, in all of the 11 trials in which mortal lives survived, mortal lives were clearly inferior to immortal lives initially but the situation eventually reversed, and, at the 400<sup>th</sup> passage duration, the number of mortal lives was, on average, 18 times greater than those of immortal lives; i.e., the mortal lives overwhelmingly prospered. These results show that an increase in heterogeneity and complexity of environmental conditions significantly improved the superiority of mortal lives with respect to immortal lives.

From the temporal aspect, it was observed that, at the initial stage, under initial conditions either homogeneous or heterogeneous, immortal lives were dominant over mortal lives in all cases, and, only when mortal lives were able to escape from extinction did they overwhelmingly dominate immortal lives without exception, although a long evolutionary time span was required. Such results indicate that if a long reproductive evolutionary time span accompanies high heterogeneity and complexity of environment, the altruistic mortal lives will become superior with respect to non-altruistic immortal lives.

These results support our hypothesis that given a sufficiently long evolutionary time span, the high heterogeneity and complexity of the terrestrial environment plays an important role in the evolutionary selection of the gene with programmed death accompanied by altruistic self-decomposition in the terrestrial ecosystem.

Life forms accustomed to existing in an optimal environment in a heterogeneous ecosystem have a greater chance of

encountering an unconformable environment as these life forms continue to reproduce and increase the size of the area in which they exist.

An unconformable environment is nothing but an environment in which reproduction is made difficult or impossible. To survive therein, such life forms must undergo evolutionary adaptation, thus acquiring novel life activity that is amenable to such environmental conditions. Immortal lives in such an environment would have no further chance to produce new individuals when the area possible for reproduction is completely filled. Therefore, before an area appropriate for reproduction fills up, there must be a mutation that provides evolutionary adaptation enabling survival in an adjacent area. Otherwise, both reproduction and evolution are blocked. As the heterogeneity in the environment increases, or as the areas with survivable homogeneous environmental conditions decrease, reproduction becomes difficult for an immortal life and the possibility of evolutionary occlusion increases.

On the other hand, mortal lives can continue the alternation of generation, even within a small area, by returning substances and space to the environment through self-decomposition and recycling. Therefore, mortal lives always possess the potential to achieve novel evolutionary adaptation by accumulating mutations without falling into the blockage of evolution. Alteration in characteristics by mutation in this case emerges as a change in the balance of the inorganic substances necessary for reproduction, an acquisition of the function of monomer intake, and a shift in optimal temperature. Thus, as the heterogeneity and complexity of environmental conditions increase, the activities of immortal lives decrease, and, at the same time, mortal lives attain superiority.

In simulations in which the initial conditions of the environment were set to be highly heterogeneous, the mortal lives overwhelmingly prospered. However, even in such cases, immortal lives were, as is natural, dominant at the initial stage of the simulation without exception. It was noteworthy that the situation completely reversed later and altruistic mortal lives that had been weak became superior.

The temporal pattern of the number of life individuals along the time line of reproductive evolution displayed particular characteristics. Under all conditions, mortal lives smoothly began reproduction and increased until the 10<sup>th</sup> passage duration at which time they entered a reduction phase. The number of mortal lives remained small for a time, then, prior to the 30<sup>th</sup> passage duration, reverted to the increase phase. When the environmental conditions became heterogeneous, the number of mortal lives monotonically increased, overwhelming the number of immortal lives.

Mutations accumulate during the alternations of generation. These mutations stochastically occur in all directions and do not necessarily acquire an evolution appropriate to a particular time and place. The environmental conditions to which the life forms must adapt are continuously changing. Therefore, a longer period, that is, eternal time, is necessary for an individual to acquire the characteristics appropriate for the varying environmental conditions conducive to mortal life as to ensure superiority within the whole ecosystem.

Non-altruistic immortal lives show superiority within a shorter time span. However, when environmental conditions are heterogeneous and complex, the prevalence of immortal lives is reduced and blocked while, over a longer time span,

altruistic mortal lives show significant superiority. This finding is highly suggestive for discussing the superiority of the altruistic gene in an ecosystem resembling a terrestrial one. The actual terrestrial ecosystem has consisted of multidimensional, multifaceted heterogeneous and complex environments microscopically and macroscopically throughout the Earth's entire several-billion-year history. The simulations under study here show that, in such environments, even primitive life forms having simple altruistic mechanisms for decomposing themselves so that they can contribute to the ecosystem in part and as a whole possess evolutionary potential for producing a teeming variety of genes and characteristics. Our results further suggest that the altruistic gene with characteristics physically appropriate for a terrestrial ecosystem endowed with high complexity and eternal time can be evolutionarily selected, can prosper and, as a result, can provide the basis for the Earth's biological diversity.

Nowak's framework (2006) of altruistic phenomena quite validly explains the altruistic behavior of higher species of animals. As a basis of such a highly developed individual-oriented altruism, the ecosystem-oriented altruism mechanism without intention is universally available to all terrestrial lives and thus functions as the basic mechanism for existent terrestrial life. This suggests that the Earth's environment might well possess the optimum characteristics for selecting the altruistic gene.

### Abstract

Human activities in outer space are producing increasing quantities of space “debris”. This well-known fact posits the question about the value and use of space technologies after their operation period has expired. Rather than calling these non-functional objects “debris”, we propose to treat them as “end-of-life allopoietic systems” with the potential of becoming autopoietic systems. In general, our utilitarian, anthropocentric, and control-oriented management of processes discourages research into emancipated, unfamiliar entities which do not (yet) appear in our ecosystems. However, outer space technology with its literal and symbolic remoteness presents an opportunity to transform utilitarian objects at their end-of-life into emancipated non-utilitarian living or life-like systems without the danger of interaction with the existing living systems of our planet. Here we outline a composite approach to the challenge.

### Composite Methodologies for Outer Space

From the beginnings of Modern age, artistic and scientific communities have been epistemologically strictly divided, each following their own methods and protocols, but concerning themselves with similar issues and topics. Recently, however, composite protocols stemming from the intersection between art and science have been emerging. These composite protocols are relevant to both spheres, but deal with issues unsolvable using methodologies of either sphere separately. It is crucial to search for new knowledge that has references in basic, natural, and applied sciences as well as in art and humanities. To achieve this, we must overcome the persistent modes and patterns of the dualist thinking inherited from Cartesianism as well as abandon the traditional conception that art deals primarily with the aesthetic and beautiful, and that it produces nice, contemplative forms that are made to please our eyes and soul. Such views on art derive from a certain age, i.e. from the 18th and the 19th century when such conception of art flourished, and when the divide between art and science has reached its peak as well. Today, it is time to embark towards a new paradigm of knowledge.

The constructivistic approach we would like to employ here is based on inter-subjectivity instead of the classical objectivity, and on viability instead of reaching one objective truth. It implies that the combination of both scientific fact and artistic/cultural manifestation leads to an abstraction, which can be projected into our cognitive reality. This abstraction of art and science in action is called the composite

projection. The composite projection works as an iteration of the process of extrapolating what we know of reality to what we think reality *should* be, then reconsidering the initial projection with new facts and developments, leading to a modified projection etc. The result therefore has multiple sequential manifestations within the realm of the possible, probable, speculative and fictional. Composite protocols thus stem from both artistic and scientific methodologies, but they are not necessarily consistent with one or the other. They facilitate a holistic understanding of particular topics that are the subject of both science and art practices. The knowledge is generated within the actual/real and conceptual/belief.

In the context of the empirically positivistic conception of science, which operates with the empirically proven, deductive truths, the application of these is guided by necessity, utility and efficiency. The result of such knowledge is therefore an applied solution within the bounds of the possible and measurable. The context of science prohibits the suspension of the possible to construct the impossible, i.e. to produce speculative narratives, fiction and fantasy (as Francis Bacon condemned the philosophy of the speculative as a harmful detour away from the truth). In this sense, speculation (when not understood as extrapolation) and fiction can be conceived as a conscious denial of fact and the reasonable, a state of belief in an idea not embedded in reality, or as a product of the anti-rational. Even so, the futuristic narratives should rely on a consensus of the possible.

Contemporary philosopher Eugene Thacker observes that there have only ever been three approaches to thinking about life: SOUL, MEAT, and PATTERN (Thacker, 2005). Within this trinity everything is deemed to be animate, living, and vital. In the time of networks, swarms, and multitudes of genetic and information technologies, the PATTERN pervades systems of all kinds and it seems to be dominant today. Despite this observation, can we rid ourselves of this trinity and dare to invent some other approach to thinking about life? The existence of our progenies beyond the edges of our heliosphere, in the absolute absence of the human and his/her effects, certainly seeks to broaden the scope of these concepts. What life is in this realm might not fit into Thacker’s trinity of soul, meat and pattern.

### Post-terrestrial Life

From its very beginning, technology has proceeded with the promise of providing us with greater control. Modernity (Modern age) promised control over nature through science

and material abundance through technology. At this point we can find the opportunity to think beyond the confines of control and surveillance, beyond the dualities of utilitarian and non-utilitarian, cause and effect, soul and meat, pattern and random, live and dead, etc. The feedback we can get from technological products that abandon the dualities of our terra-thinking, which in fact owes a lot to Cartesian conceptions, is entirely unpredictable.

The “end-of-life” space objects are terrestrial materializations of human thought having potential to become the emancipated, functional units, capable of cognition and, consequently, of identity. Terrestrial sensory probes at the edges of our solar system, the farthest-reaching manifestations of humanity, were designed to fulfill strictly scientific purposes. However, the ultimate fate of these objects, beyond relentlessly serving humanity with data, had not been determined at their launch. The remoteness and the ebbing life of these extensions of the human species are gradually turning the augmentations into independent objects.

Our challenge is to nurture the teleology of space probes beyond their initial purpose. We aim to explore possible modifications of existing and future space probes to turn allopoietic instruments into resilient, self-repairing, robust, autonomous, energy efficient, adaptable systems, all of which are properties current technology lacks, but living systems possess.

### **The Authentic Environment**

To create artificial life on Earth is a proof-of-principle; proof that we understand living systems to the extent we are able to recreate them. This positivistic approach, however, does answer the question *why* one should attempt to do so, since life has been ubiquitous and resourceful through both space and time in terrestrial environments. Outer space is in fact the authentic environment of artificial life, because life (as far as we know) has not been able to colonize it on its own.

We begin to apply the current knowledge of resilient self-organizing systems to the construction of the next generation of space probes. Unlike scientists, who would equip the next probes with ever better and more complex systems designed to carry out scientific experiments, we foresee the addition of a simple entity, which can withstand the conditions in outer space, but also with the ability to adapt, if it encounters environmental changes; made up of a self-repairable matrix, coined from autonomous technology and simple living (or life-like) systems; working in a symbiosis to absorb entropy and fight decay.

### **Emancipated Space Technologies**

Distance is a tool of scientific and artistic contemplation. Creating progeny that is foreign and non-utilitarian in every respect has great philosophical value as it presents us with a (bio)technological version of the “overview effect”. The alienation induced by this other has the potential to transform the familiar and recalibrate the human condition, urging us to revise the dominant but often exclusionary humanist values.

Humankind, in awe of scientific knowledge, humanistic understanding and artistic possibilities, can produce an

unthinkable civilizational value. Enabling autonomous processes out of our reach is a civilizational step that can lead to a better understanding not only of what we know but also what we don’t.

## Abstract

This paper concerns the evolution of altruism in a population of autonomous agents. It explores the relation between altruistic behaviours and spatial dispersion in open-ended evolution whenever energetic constraints must be addressed. A method derived from Embodied Evolution is used to model the spatial interactions between agents from an individual perspective. Firstly, results show that spatial dispersion and levels of altruism are strongly correlated, which confirms theoretical results from biology, but also that this relation may be overshadowed by the complex interactions at work in the ecosystem. Secondly, this paper investigates how robust altruistic behaviours able to cope with various environmental pressures may be evolved. In particular, it is shown that there is a trade-off between efficiency and versatility: the ability to perform well across a wide range of environmental conditions often comes at the cost of sub-optimal performance in terms of survival, especially when compared to more constrained (and less versatile) evolved strategies.

## Introduction

Cooperative behaviours are defined by the realisation of actions by an agent which brings benefits to other agents. This paper focuses on altruism, which is a special type of cooperative behaviour characterised by the sacrifice of one agent for the benefit of others (Lehmann and Keller, 2006). This is different from mutual cooperation as the fitness of an agent is permanently impaired by such acts. This type of behaviour may look counter-intuitive from the viewpoint of the theory of evolution as an altruistic agent reduces its own chance of survival in order to increase the chance of survival of other agents. However, such altruistic behaviour is found in multiple biological species, and multiple works have investigated the conditions and mechanisms at play in its evolution.

A common way to explain the evolution of altruism in biology is to consider the survival of genes rather than individuals. In this context, individuals are vehicles for genes that try to survive (Dawkins, 1976). This aspect is captured by the idea of the inclusive fitness which considers that the fitness of a particular individual depends both from its own action and from the actions of its related kin (Maynard Smith,

1964).

Classic approaches in game theory (Maynard Smith, 1974) and adaptive dynamics (Diekmann, 2004) have been used to explore multiple causes that favour the evolution of altruism. The most studied mechanisms are kin selection (Maynard Smith, 1964), group selection (Wynne-Edwards, 1986), tag recognition (Holland, 1996) and environment viscosity (Hamilton, 1964). In particular, kin selection stresses that genes responsible for altruistic behaviours can increase in frequency when there is a chance that beneficiaries of such altruistic acts also carry such genes. In other words, kin selection hypothesizes that the inclusive fitness of an individual is increased if it is genetically close to its neighbours. Kin selection has long been a central idea in the evolution of altruism, and recent works have shown that several other mechanisms (such as group selection) are actually much more related to kin selection than originally expected (West et al., 2007; Grafen, 1984; Queller, 1994; van Baalen and Rand, 1998). Moreover, explicit behavioral strategies have been shown to increase kin selection, such as kin recognition and spatial dispersion (West et al., 2007). In particular, a low spatial dispersion naturally favors reproduction among kins.

From the perspective of artificial evolution, several works have previously addressed the evolution of altruism (Waibel et al., 2009), and of communication (Floreano et al., 2007) (a particular kind of cooperative behaviour) with regards to the level of selection (at the level of the team or the individual), and the composition of teams (homogeneous or heterogeneous). These works successfully show cooperative behaviours could evolve from team level selection or by enforcing homogeneous teams, which is coherent with results previously established in theoretical biology (cf. (Hamilton, 1964)). However, these works rely on a fixed selection scheme (rather than letting it evolve) which prevents studies of particular dispersion strategies that could influence the level of homogeneity and relatedness in the population.

This paper addresses the evolution of spatial dispersion behaviour, in the context of a harvesting task that requires altruistic cooperation among individuals. The question under

scrutiny is to understand how spatial dispersion may evolve when altruistic behaviour comes as a requirement for the population to survive. In particular, it is expected that there is a correlation between the consumption strategy and the spatial dispersion evolved: the more altruistic the individuals, the less spatial dispersion should be observed (Taylor, 1992)). However, questions remain open as to whether such behaviours may be observed easily in nature, and what kind of behaviours may be evolved in term of consumption and spatial dispersion strategies.

The approach followed in this work builds on an existing framework for *in silico* experimental evolution for individual-based modeling and simulation undergoing an open-ended evolutionary process (i.e. long term adaptation in an open environment). In this context, the ability for an individual to survive and pass its genotypic material depends solely on its interaction with other individuals and with the environment, comparably to Dawkins' selfish gene metaphor (Dawkins, 1976) or TIERRA's open-ended evolutionary process (Ray, 1992). Therefore, it is possible to investigate the particular dispersion strategies which comes from a trade-off between harvesting and genotypic material diffusion.

In the following, the experimental setup is described, along with methodological tools and implementation details. A statement of the working hypotheses and outline of the experiments follows. Then, the experiments are described and discussed. Firstly, the possible correlation between spatial dispersion and level of altruism is investigated. Secondly, the trade-off between evolving either efficient or versatile strategies is studied. Finally, the last Section concludes this work and takes a broader perspective from this work, considering implications both from the theoretical viewpoint wrt. biology and from the practical viewpoint wrt. collective adaptive systems.

## Method

### Open-ended Evolution with mEDEA

The **mEDEA** algorithm, as in *minimal* Environment-driven Distributed Evolutionary Adaptation, was initially introduced in (Bredeche and Montanier, 2010). It performs as an evolutionary adaptation algorithm that can be distributed over a population of agents (i.e. each agent in the population runs the same algorithm, but carries different genomes). While it has been originally designed for collective robotic systems, it can be (and has been) used as a modeling and simulation tool for studying spatial interactions between agents. In previous works (cf. Montanier and Bredeche (2011)), mEDEA has been used to study the impact of genotypic relatedness on altruistic cooperation, in particular whenever genotypic relatedness between individuals is enforced through kin recognition (i.e. explicitly favoring the reproduction of closely related individuals).

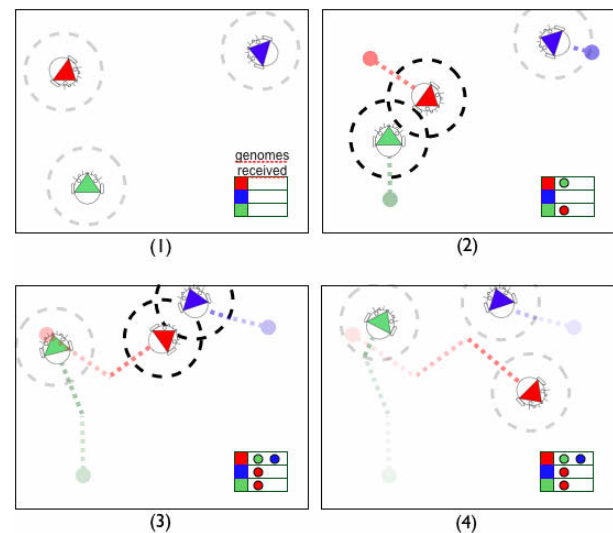

Figure 1: The mEDEA algorithm: a simplified illustration. (1): generation starts, genome reservoirs are empty; (2) and (3): agents move around (each agent is controlled by its own active genome) and exchange mutated genomes when close enough; (4): generation ends - the red genome has spread more and thus have higher probability of being selected (in this case, probability is indeed  $p = 1$  in two agents while the two other genomes only get  $p = 0.5$  in one single agent). After selection, all the reservoirs are emptied. Note that the next generation will contain slightly mutated copies of the original genomes.

Figure 1 provides an illustrative example of how mEDEA works (see (Bredeche and Montanier, 2010) for a complete description of the algorithm). Each robotic agent contains an *active* genome, which (indirectly) controls the agent's behaviour, and a *reservoir of stored genomes*, which is empty at first. At each time step (or iterations), each agent *broadcasts* in a limited range a *slightly* mutated copy of its active genome (gaussian mutation) and stores genomes received from neighbours, if not already stored. At the end of a generation (i.e. a pre-defined number of iterations), each agent "forgets" its active genome and *randomly* picks one genome from its reservoir of stored genomes (if not empty). Then the reservoir is emptied, and a new generation starts. This algorithm is running independently within each agent in the population. By this mean, agents' behaviours differ depending on each agent's current active genome.

Therefore, selection pressure occurs at the population level (the more a genome spreads itself, the higher the probability it will generate offsprings) rather than at the individual level (random sampling). Genomes survive only through spreading (as an active genome is automatically deleted locally at the end of a generation) and individual may get better over time as conservative mutations generate new candidates that explore alternative behavioural strategies.

Figure 2: Snapshot from the simulator: food items (circles), agents (dots) and obstacles

On the one hand, mEDEA resembles other open-ended evolutionary setups such as TIERRA (Ray (1991)) as selection pressure occurs through interactions between agents in their environment rather than by explicitly computing a fitness value (such as a metabolic function). On the other hand, relying on a maximum number of active mobile agents makes it possible to set an upper bound in term of computational time required for the simulation, in a similar fashion as it is by setting a maximum number of cells in AVIDA (Ofria and Wilke, 2004). In mEDEA, each genome competes for accessing a limited set of resources: the population of robotic agents.

### Setup

The setup used in this work (displayed in Figure 2) features simulated robotic agents which harvest food items from the environment in order to remain active. Each robotic agent consumes a fixed amount of energy at each iteration, and has a limited energy storage capability.

Each agent can be in three different states: active, dead or listening. At the beginning of a run all agents are in the active state, i.e. they are using an active genome (randomly generated in the range  $[-1.0; 1.0]$ ), and their energy level is greater than 0. If during a generation an agent runs out of energy, it switches to the dead state. In this state the agent has no active genome, remain stationary, and cannot store genomes from robots passing by. The dead state is maintained for one generation, after which the agent switch to a listening state. In this state the agent doesn't move but stores the genomes broadcasted by agents in its neighbourhood. This state is maintained during one generation. If at the end of a generation in listening state the reservoir is still empty, the agent will remain in listening state for another generation, and so on. Any agent with an empty reservoir at the end of a generation switches to the listen state.

Food items are randomly placed in the environment. Once a food item has been harvested it becomes unavailable for some time, termed  $EP_{Lag}$  (the regrow delay). This term depends linearly on the energy harvested from it as shown in Equation 1:

$$EP_{Lag} = E_{harvested} / EP_{eMax} * EP_{LagMax} \quad (1)$$

$EP_{eMax}$  is the maximal amount of energy that can be harvested from a food item by an agent.  $E_{harvested}$  is the energy actually harvested from the food item by an agent.  $EP_{LagMax}$  is the maximal regrow delay of a food item.

Environmental pressure can be changed from low to high by setting the value of the  $EP_{LagMax}$  parameter. Large  $EP_{LagMax}$  values result in longer regrow delay (i.e. larger  $EP_{Lag}$  values) whenever a food item is completely harvested, which decreases the number of food items available for some time.

### Monitoring Consumption Strategy

An agent may display an altruistic behaviour by harvesting only part of a food item. Such a consumption strategy is costly in terms of fitness (as it might run out of energy), and is of benefit to other agents (the food item will regrow faster). On the contrary, selfish agents will completely harvest any food item, which is likely to increase their chance to survive, but also reduces the number of food items available to other agents.

The consumption cost an agent accepts to pay is measured by the difference between how much energy could have been harvested by the agent (in order to completely fill the battery), and how much was really harvested. Equation 2 gives a definition of the consumption cost:

$$Cost = \max(0, \min(EP_{eMax}, r_{E_{max}} - r_{E_{now}}) - E_{harvested}) \quad (2)$$

$EP_{eMax}$  is defined as before (i.e. maximal energy in a food item),  $r_{E_{max}}$  is the maximal energy level of an agent,  $r_{E_{now}}$  is the current energy level of the agent, and  $E_{harvested}$  is the energy harvested by the agent from the food item.

While a selfish agent shall have a consumption cost of zero, an altruistic agent should ideally be able to perform a trade-off between its altruistic nature and its survival needs. Therefore, the consumption cost of altruism can be seen as the agent's level of sacrifice which is continuous (a quantity of energy) rather than discrete (eat or don't eat).

As a last remark it should be noted that the consumption strategy is but one way to monitor altruistic behaviours. As an example, two different consumption strategies, each combined with a different exploration strategy (travelling speed, area coverage) may well end up with the same number of food items available at any time (slow but greedy vs. fast but frugal agents). The next paragraph investigates how to take into account spatial dispersion strategies, in addition to consumption strategies already considered.

### Monitoring Spatial Dispersion

Spatial dispersion may impact harvesting strategies as well as altruistic cooperation in various way as low dispersion

(i.e. remaining in the same region) may both favour exploitation of the same food items as well as increasing kin selection (and therefore impact the level of altruism, as long known since Maynard Smith (1964)). In order to account for spatial dispersion, we devise a measure to approximate the area covered by one agent during its lifetime.

In order to do so, the environment is divided into squared regions. For each agent, the number of regions is counted during its lifetime, and the *AreaCovered* value is computed following Equation 3:

$$AreaCovered = \frac{\#VisitedCells}{\#Cells \times lifetime} \quad (3)$$

In the following, the environment has been divided in 33920 cells of 4 by 4 pixels. The theoretical minimal value of this measure is  $1/(\#Cells \times lifetime) = 7.34258 \times 10^{-08}$ . The maximal value depends on agents maximal speed ( $Max_{Agent_{speed}}$  given in fraction of cell area), and is given by Equation 4:

$$Max_{AreaCovered} = \frac{Max_{Agent_{speed}}}{\#Cells} \quad (4)$$

### Working Hypotheses

Firstly, the link between consumption strategies and spatial dispersion will be investigated by monitoring spatial dispersion whenever a pre-defined consumption strategy is used. The expected result is that the level of altruism displayed during consumption of food items should be (negatively) correlated with spatial dispersion (the higher the consumption cost, the lower the dispersion) as lower dispersion theoretically increases genotypic relatedness, which is a key to altruistic behaviour. However, it remains to be investigated if such results can actually be observed as survival becomes more challenging as environmental pressure increases (i.e. spatial dispersion may not be solely driven by altruistic motivation).

In practical, this will be done by enforcing the amount of energy that is *left* when harvesting a food item. In Equation 2, this corresponds to setting a value for  $E_{harvested}$  so that the *Cost* paid is equal to the "fixed" cost expected. In this paper, two different fixed costs, each close to one particular extreme consumption behaviour, are investigated: whenever a food item is harvested, either 5 (slightly altruist) or 40 (very altruist) units of energy are left over on a total of the 50 units of energy a food item can provide, implying different consequences on the food item's delay to regrow. These *fixed cost* consumption strategies will be referred to as *cost* = 5 and *cost* = 40 consumption strategies in the next Section.

Secondly, the possible benefits of leaving to evolution both the consumption strategy *and* the spatial dispersion strategy will be investigated. It is indeed not clear that letting

both strategies evolve should lead to better survival strategies, as evolution may face a more difficult challenge due to an increased number of degrees of freedom. In practical, the consumption cost to be paid when a food item is harvested will be left to the robot to decide and both consumption cost (cf. Equation 2) and spatial dispersion will be monitored. The expected result is that evolving both consumption cost and spatial dispersion may possibly lead to a richer set of behaviours whenever environmental pressure varies, though possible benefits remain to be identified. This consumption strategy will be referred to as *dynamic cost* in the next Section.

## Results

### Technical Details

A Multi-Layer Perceptron (MLP) is used to encode the controller of each robotic agent. The input layer is composed of 12 inputs (8 for distance sensors, 1 for the direction to the closest energy point, 1 for the distance to the closest energy point, 1 for the battery level of the agent, 1 to detect the presence of an energy point under the agent), the hidden layer is composed of 5 neurons, and the output layer is composed of 3 neurons (rotational speed, translational speed and amount of energy to be harvested (used only if a food item is within reach)). The output neuron for energy harvesting is not taken into consideration when a fixed cost is used. The weights of the MLP are decoded from the active genome of the agent. A gaussian mutation is used, and initial weights are set randomly around zero. The  $\sigma$  parameter for mutation is evolved, and a minimal value (0.01) is fixed to avoid obtaining a population of clones

All experiments are performed with RoboroBo, a fast open-source multi-robot simulator (Bredeche et al., 2013). In order to ensure the reproducibility of the experiments presented in this paper, the full implementation is available online<sup>1</sup> and parameters used are summarized in Table 1. One run takes approximately one hour to be performed using one core of a quad-core 2 CPUs Intel 2.26 GHz processor. All experiments presented in this paper are performed on a computer cluster equipped with such processors. For each setup considered in the next section results, each Figure results from a compilation of 500 independant runs, and statistical significance is tested using the Wilcoxon signed-rank test (Wilcoxon, 1945).

### Evolution of Spatial Dispersion Strategies

In order to obtain results on a large range of environmental pressures, the experiment starts with a low environmental pressure ( $EP_{Lag_{Max}} = 25$  iterations) until the 400000<sup>th</sup> iteration. After this, the environmental pressure

<sup>1</sup>[http://pages.isir.upmc.fr/evorob\\_db/moin.wsgi](http://pages.isir.upmc.fr/evorob_db/moin.wsgi)

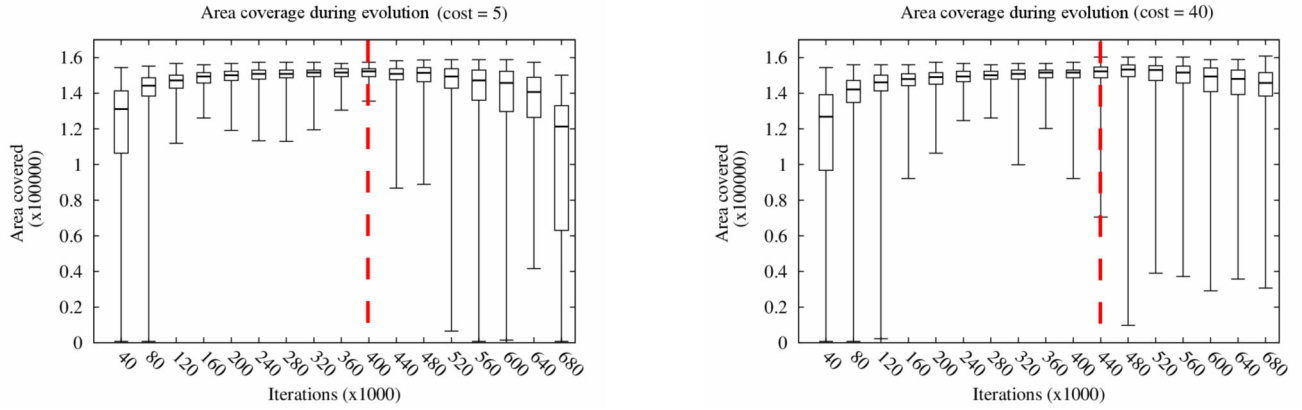

Figure 3: Area coverage measured when the cost of altruism is fixed to 5 (left) and 40 (right) and the pressure of the environment increases by step of 80 iterations every 4000 iterations from iteration 400000 (before the environmental pressure is  $EP_{LagMax} = 25$  iterations).

Parameter	Value
arena width and length	$1024 * 530$ pixels
lifetime (i.e. generation duration)	400 iterations
selection scheme	random
population size	100 agents
agent size	1 pixel
proximity sensor range	64 pixels
radio broadcast signal	32 pixels
agent rotational velocity	0.52 rad/iteration
agent translational velocity	3 pixels/iteration
genome length	84 real values (83 MLP weights + $\sigma$ )
variation operator	Gaussian mutation with $\sigma$ parameter
cells size	4 by 4 pixels
theoretical max area	$2.21108 \times 10^{-5}$
theoretical min area	$7.34258 \times 10^{-8}$
$EP_{LagMax}$	50
number of energy points	800
$r_{eMax}$	400
energy consumption	1 per iteration

Table 1: Parameters for experiments.

slowly increases every 4000 iterations (10 theoretical generations) until the population goes extinct (i.e. no genome left to exchange). Each increase of the environmental pressure is done by a fix amount of 80 iterations in the regrow delay ( $EP_{LagMax}$ ). As an example,  $EP_{LagMax} = 105$  iterations at the 404000<sup>th</sup> iteration of the simulation, and  $EP_{LagMax} = 185$  iterations at the 408000<sup>th</sup> iteration.

Results obtained when two harvesting strategies with fixed costs of 5 (less altruistic strategy) and 40 (more altruistic strategy) are used are presented in Figure 3 (500 runs for each setup). With both strategies the area dispersion evolved is increasing until iteration 400000<sup>th</sup> and decreasing after ( $p$ -value  $< 0.05$  for comparison of iteration 400000 and every iteration after 560000). This shows that different spatial dispersion strategies are displayed through evolution depending on the consumption strategy used and the environmental pressure at hand.

The differences between spatial dispersions evolved under different consumption strategies is expected from results obtained in biology (as said before). However, results shown here are contradictory with theory: spatial dispersion is shown to be higher for the more altruistic con-

sumption strategies when challenging environment are considered (while kin selection, favored by lower dispersion, should be paired with an increased altruistic behaviour (Taylor, 1992)). Rather than contradicting well established theoretical results, individual based modeling and simulation actually points out the complex interactions between individuals and the environment. Indeed, dispersion strategies may be influenced by much more than just acting on genotypic relatedness. The number of active agents, the availability of energy points, and the regrow delay are all possible causes to explain a particular dispersion strategies. Therefore, one question remains: in a comparable setup (i.e. removing all other possible causes), how does dispersion strategies compare when evolved with different fixed consumption strategies.

### Fair Comparison of Dispersion Strategies

In order to compare results from the two setups considered previously, agents' spatial dispersions are measured in a similar environment. The environment used for comparison features a consumption cost artificially fixed to 0 (whatever the initial consumption cost used during evolution) and a low environmental pressure ( $EP_{LagMax} = 25$  iterations). Moreover, genome transmission and selection are shut down, and robots continue to run even if energy is depleted. This makes it possible to compare the different behavioural strategies by *replaying* evolved genomes with all other parameters set to similar values. The following replay procedure is defined: (1) genomes from the 600000<sup>th</sup> iteration of a given run are randomly sampled to assemble a population of 100 individuals ; (2) this population is embodied in 100 robots (one genome per robot) (3) The spatial dispersion of these robots is measured during 40000 iterations.

For each fixed cost strategy considered earlier, genomes

are extracted from 20 runs selected randomly among the 500 discussed earlier, and replayed following the procedure described above. The replay procedure is repeated 20 times for each setup (total of 800 replays). In addition, we devise a third type of behaviour, which stands as a control experiment: agents using random controllers. Random translational and rotational speeds are assigned to 100 agents at each iteration, and spatial dispersion is measured for 40000 iterations. This is inspired from typical tests in ecology field studies where geographic tracking of animals positions are evaluated wrt. brownian motion (Borger and Fryxell, 2012). This control experiment is termed *random behaviour*, and is also performed 800 times.

Figure 4: Area coverage for three consumption strategies when replayed, and for runs using random movements. All area coverage are significantly different:  $p - value < 0.05$  for comparisons between each boxplot.

The median results for each fixed consumption strategy and the random behaviour are presented in Figure 4. As expected, both strategies evolved under environmental pressure (cost fixed to 5 and cost fixed to 40), display higher level of dispersion than random movements. Then, comparing the fixed cost consumption strategies, it is shown that the area covered is significantly higher when a lower level of altruism is used during evolution ( $p - value < 0.05$  between a cost fixed to 5 and a cost fixed to 40). As a consequence, this confirms expected results from theory: there is indeed a negative correlation between spatial dispersion and consumption behavior: enforcing a consumption strategy which displays altruistic behaviour leads to lower spatial dispersion, which is expected to increase kin selection, and thus altruistic behaviour among closely related individuals.

Typical runs for each behaviour studied (i.e. runs at the median), are shown in Figures 5(a), and 5(b). In these two Figures, which can only be interpreted in light of the previously shown quantitative analysis, illustrate slight but visible differences in spatial dispersion. Trajectories obtained with a highly altruistic consumption strategy ( $Cost = 40$ ) dis-

play more localized behaviours (i.e. robot circling around in the same area) and fewer wandering trajectories. Counting the average number of encounters per agent also advocates for local interactions: there are significantly less encounters for the  $Cost = 40$  strategy than for the less altruistic, more exploratory,  $Cost = 5$  strategy ( $p - value < 0.05$ , Wilcoxon test).

### Evolving Consumption and Dispersion Strategies

In this last part of the paper, we investigate the impact of evolving both the consumption strategy and the dispersion strategy. By doing so, we intend to address the following questions: (1) What kind of (consumption and dispersion) strategies can be expected when evolved under different environmental pressures ; (2) What are the possible benefits and drawbacks of evolving the consumption strategy rather than enforcing an ad hoc consumption strategy.

As before, 500 runs are performed. The setup is similar to the previous setups for fixed cost, except that the cost of altruism is now chosen by the robot controller. This setup is termed "Dynamic Cost" has the cost paid may change any-time and depends from evolution (i.e. the controller output fixing the amount of energy taken from a food item is actually used). Figure 6 shows the boxplot results for consumption costs paid and area dispersion evolved by all agents throughout evolution. As before, the environment becomes gradually more challenging starting iteration 400000, and stops when all runs have gone extinct.

A notable difference is that during the first part of the runs, the consumption costs paid stick to zero, which is not unexpected as there is no benefit at being altruistic in an environment that represent an easy challenge. The consumption cost paid then abruptly changes as soon as the environmental pressure increases ( $p - value < 0.05$  for comparison between iteration 400000 and iteration 440000). It then fluctuates around a value of 5 until iteration 680000, and remains significantly higher than at the beginning of the run ( $p - value < 0.05$ , comparing results from iteration 400000 and any iteration afterwards). Moreover, the final value (at iteration 680000) is similar to the value obtained at iteration 440000 ( $p - value = 0.31$ ). Hence, there appears to be two stable values (either no altruism ( $Cost = 0$ ) or low altruism ( $Cost \approx 5$ )) for consumption cost depending on the challenge posed by the environment.

Regarding spatial dispersion, Figure 6-right shows that the area covered by each agent levels up, and then off, until iteration 400000. Then, as environmental pressure starts to increase, the area covered is continuously decreasing, and ends up as significantly lower beyond iteration 560000 ( $p - value < 0.05$ , comparing area covered at iteration 400000 and any iteration from 560000).

In order to compare the behaviours obtained with a dynamic cost, replay sessions are performed in the exact same fashion as it was for the fixed cost setups. Quantitative re-

Figure 5: Trajectories from median runs for consumption strategies of cost=5 (left) and cost=40 (right).

Figure 6: Consumption cost of altruism (left) and area coverage (right) measured when the Consumption cost is dynamic and the pressure of the environment increases by step of 80 iterations every 4000 iterations from iteration 400000 (before the environmental pressure is  $EP_{LagMax} = 25$  iterations).

Figure 7: Area coverage for two consumption strategies when replayed, and for runs using random movements. All area coverages are significantly different.

sults obtained by all consumption strategies studied are presented in Figure 7. Results obtained with the dynamic cost strategy is different from all other strategies ( $p$  - value < 0.05 for comparisons between each cost strategy). This con-

firms the impact of cost strategies on the evolution of behaviours.

Figure 8: Number of active runs when the environmental pressure is increasing.

Another way to study the differences between different cost strategies is to observe the extinction of runs : that is,

for a given iteration, how many runs is there with at least one active agent. Figure 8 shows the number of active runs for all three setups considered ( $Cost = 5$ ,  $Cost = 40$  and dynamic Cost) starting iteration 400000, that is when environmental pressure starts to gradually increase. From this figure, several particular situations arise: the  $Cost = 5$  strategy dominates before iteration 580000, and is replaced by the  $Cost = 40$  strategy around iteration 600000 and until iteration 700000. Afterwards, only the  $Cost = 40$  and dynamic Cost remain for another 100000 iterations until all runs for both go completely extinct. Though the dynamic Cost strategy goes a little further than the  $Cost = 40$  strategy, there are too few runs left to make any statistically significant remark between the two setups beyond iteration 700000. Most notably, the dynamic Cost strategy is nearly never completely dominated by the two other strategies. As such, it appears that relying on a dynamic cost strategy provides some kind of trade-off between optimal performance in specific contexts and versatility in various contexts, without having to take the risk of guessing which cost must be paid prior to evolution.

## Conclusion

In this paper, we have studied the importance of spatial dispersion during the evolution of altruistic cooperation in a population of autonomous agents. This work followed an individual-based modelling and simulation approach using the mEDEA algorithmic framework for open-ended evolution, which enables to study the actual evolution of individual spatial dispersion and consumption strategies in the context of a harvesting task.

Firstly, well-established theoretical results on kin selection in the evolution of altruism were confirmed experimentally regarding the negative correlation between the level of altruistic behaviour and spatial dispersion. However, our work revealed that such a confirmation may not come for free when individual modeling and simulation is considered as the complex interactions between the population and its environment may provide contradictory results at first glance. This result is important as it may have an impact on field observation from nature, where the level of spatial dispersion may fail to directly explain the occurrence of altruistic behaviour.

Secondly, we showed that there is a trade-off between setting ad hoc mechanisms (here, the strategy used when eating a food item) and letting such mechanisms to evolution. On the one hand, results show that the more there is left to evolution, the less likely optimal behaviour may be reached (compared to *a priori* carefully crafted strategies). On the other hand, fully evolved strategies turn out to be more versatile, i.e. showing good performance in a larger set of contexts, and require less prior knowledge compared to more constrained evolutionary setups.

Lastly, this paper intends to contribute both to theoretical biology, by providing new results from an individual-based

modeling perspective where spatial dispersion is the product of open-ended evolution, and to collective adaptive systems, as the algorithm used throughout this paper may straightforwardly be implemented onto real robots (and has already been, albeit for a different problem).

## Acknowledgments

Experiments presented in this paper were carried out using the Grid'5000 experimental testbed, being developed under the INRIA ALADDIN development action with support from CNRS, RENATER and several Universities as well as other funding bodies (see <https://www.grid5000.fr>). This work was made possible by the Alain Bensoussan Fellowship Programme.

# Environmental Feedback Drives Multiple Behaviors from the Same Neural Circuit

## Abstract

The ability of a single neural circuit to produce qualitatively distinct behaviors is typically attributed to some adaptive mechanism in the circuit itself. However, neural circuits are also embedded in particular bodies and environments, and feedback through the sensorimotor loop may also serve to drive behavioral differentiation. Here we explore the ability of a single neural circuit to produce qualitatively different behaviors based on changing patterns of environmental feedback. Agents equipped with two sets of effectors and controlled by fixed neural circuits are evolved to catch circles under three different motor conditions. In one condition, the agent must coordinate both sets of effectors, while in each of the other conditions one set of effectors is lesioned and the agent must rely on the other set alone to accomplish the task. A detailed behavioral analysis of the best evolved agent is reported, providing numerous insights into its evolved behavioral mechanism. The agent is found to produce significantly different motor outputs in each of the three conditions, to rely on continuous environmental feedback for successful behavior, and to switch flexibly between different behavioral conditions.

## Introduction

The ability of a single neural circuit to produce multiple qualitatively distinct behaviors, referred to as *multifunctionality*, is typically thought to be due to some adaptive mechanism in the neural circuit itself. For example, a single neural circuit may produce multiple distinct behaviors as a result of synaptic plasticity, neuromodulation, or intrinsic multistability (Briggman and Kristan, 2008; Getting, 1989; Morton and Chiel, 1994). In all of these mechanisms, the primary source of behavioral differentiation is assumed to be the neural circuit itself, while the role of bodily and environmental context is taken to be of secondary importance. However, in the past few decades, researchers from a variety of disciplines—including artificial intelligence, neuroscience, philosophy of mind, and cognitive science—have increasingly emphasized the importance of *situatedness* and *embodiment* for the production of intelligent behavior (Brooks, 1991; Clark, 1995; Pfeifer and Bongard, 2007; Beer, 2008). Broadly speaking, situatedness refers to the role played by

an agent's ongoing interactions with its immediate environment in shaping behavior. For example, a situated agent may substitute actions in the world for actions in the head, effectively offloading aspects of cognitive processes to the environment (Kirsh and Maglio, 1994; Hutchins, 1995). Embodiment refers to the influence that the structure and properties of an agent's body have on its behavior. For instance, embodiment allows an agent to actively select and structure the information that it receives from its environment (Lungarella and Sporns, 2005; Pfeifer et al., 2007; Polani et al., 2007).

But how much can situatedness and embodiment really influence behavior? In particular, can different bodily or environmental contexts produce qualitatively different behaviors from the same neural circuit, or only slight variations? As a corollary, how important is it for cognitive scientists to take into account the bodies and environments of intelligent agents in order to understand the mechanisms that produce their behavior? A recent study by Izquierdo and Buhrmann (Izquierdo and Buhrmann, 2008) explored these questions in a radical way, by evolving model neural circuits to exhibit qualitatively distinct behaviors when their bodies and environments were literally switched. Specifically, building upon earlier studies where neural circuits were evolved for walking (Beer and Gallagher, 1992; Beer, 1995a; Beer et al., 1999) and chemotaxis (Beer and Gallagher, 1992), Izquierdo and Buhrmann evolved individual circuits to perform both tasks. In one condition, the neural circuits were embodied in a simple legged agent and evolved to exhibit walking behavior. In a second condition, the same neural circuits were embodied in an agent with a chemo-sensor and were evolved to perform chemotaxis. Crucially, the neural circuits were evolved with fixed synaptic weights, so that there was no intrinsic adaptive mechanism in the circuits themselves. Additionally, the circuits did not receive any explicit signal indicating which of the two behavioral conditions they were in. Thus, the only information that the circuits received about the appropriate behavior for their current context, and the only means by which the circuit could generate these distinct behaviors, was via changing patterns of feedback through the body and environment.

Izquierdo and Buhrmann also performed a dynamical analysis of the best evolved circuit, and found that the same region of autonomous dynamics was utilized by the circuit in both behavioral conditions. In other words, the different behaviors of the circuit could not be tied to different regions of autonomous dynamical behavior, as one might conventionally expect. Rather, the distinct behavioral patterns were shown to arise solely through different patterns of feedback on multiple timescales within the behaving brain-body-environment system. Thus, the primary objective of this study was to demonstrate the profound importance that feedback through the body and environment can have on producing different behaviors from the same neural circuit, and in this it succeeds admirably.

However, it would also be desirable to demonstrate the same idea without requiring the radical changes of swapping bodies and environments, especially since biological circuits exhibit multifunctionality often times without such changes. In particular, one would like to demonstrate that changing environmental feedback alone suffices to evoke different behaviors, while body and environment remain the same. In general terms, behavior is the product of a complete brain-body-environment system, and thus the generation of multiple behaviors can be driven by changes in any part of that system. Thus, while multiple behaviors can be produced, as in the case of Izquierdo and Buhrmann, by changing multiple parts of the brain-body-environment system simultaneously, multiple behaviors can also be produced by changing only one element of the brain-body-environment system at a time. In addition to changes in the underlying neural system (Briggman and Kristan, 2008), such changes can also include modifications to an agent's sensors (Buhrmann et al., 2013), actuators (Nolfi, 2009), or overall body morphology (Fine et al., 2007; Auerbach and Bongard, 2009).

The goal of this project was to achieve a simple demonstration of how changes in an agent's actuators can drive multiple behaviors, and to begin exploring exactly how multiple behaviors can be produced through changing patterns of environmental feedback. In this study, agents are evolved to catch circles falling towards them from above. The agents are equipped with two set of effectors, and are evolved to catch circles under three behavioral conditions. In the first condition, the agent must coordinate the actions of both sets of effectors to successfully catch the objects. The other two conditions are formed by "lesioning" one or the other of the agent's effectors, such that the agent must perform the task with only one functional set of effectors. Thus, in each of the three conditions, the agent must generate radically different behaviors in order to accomplish the task. Moreover, as in (Izquierdo and Buhrmann, 2008), the neural circuit controlling each agent has fixed synaptic weights, and the agent receives no direct information regarding which or the three conditions it is in, i.e., there is no signal indicating that one or the other of its effectors have been lesioned. As a result,

Figure 1: The agent and environment. The agent moves horizontally using two sets of effectors while circles fall towards it from above. The agent's sensory apparatus consists of an array of seven distance sensors.

the agent must rely solely on the time-varying perceptual feedback that it receives as a result of its actions in the environment in order to successfully perform the task.

In the next section, we describe the model agent and environment that were used in this study and describe the evolutionary protocol that was used to evolve agents. In the third section, we then describe results from a series of experiments exploring the behavior of the best evolved agent. Finally, in the fourth section, we summarize the results from these experiments and then conclude.

## Methods

The model agent used in this study has a circular body with a diameter of 30, and an array of 7 distance sensors equally spaced over an angle of  $\frac{\pi}{3}$  radians on the agent's top side (Figure 1). Each distance sensor has a maximum length of 220. Distance sensors take on values inversely proportional to the distance at which their corresponding rays intersect objects in the environment. This part of the agent model is essentially the same as in previous work on categorical perception (Beer, 1996, 2003; Williams et al., 2008). The agent is positioned along the bottom edge of a planar environment and is able to move horizontally in either direction. The agent's motion is produced by two sets of effectors. One set of effectors, henceforth referred to as *wheels*, propel the agent in either direction with a pure force having a maximum magnitude of 6. The other set of effectors control a simple model leg that the agent can use to walk in either direction. The leg is controlled by three effectors, with two governing left and right swing and the third controlling the position of a foot. When the foot is up, the two swing effectors allow the agent to swing the leg through a range of  $[-\frac{\pi}{4}, +\frac{\pi}{4}]$  with a maximum angular velocity of 5, while the body remains still. If the foot is down, the swing effectors can exert a force to move the agent either left or right. The leg can exert a maximum force of 8 and a maximum torque

of 5 to move the body. When the leg exerts a force on the body, it stretches elastically so that the body's vertical position remains unchanged. However, if the leg reaches either extreme of the allowed angular range of motion, the agent's velocity immediately drops to 0. The agent's motion is also impeded by a constant frictional force of 1, which must be overcome by the effectors in order to produce movements.

The agent's task is to catch circles that fall towards it from above. Specifically, circles of diameter 40 fall towards the agent from an initial vertical distance of 220 (the maximum length of each ray sensor) and at a constant vertical velocity of -1. The agent is to catch each circle by minimizing its horizontal separation from the circle when the circle completes its fall. During evolution, agents were evaluated on 10 circle presentations in each of three motor conditions (explained momentarily), uniformly distributed over a range of horizontal offsets between  $[-150, +150]$  relative to the agent. The agent's performance on each trial is given by:

$$\frac{150 - d}{150}$$

where  $d$  is the distance between the agent and the circle when the circle completes its fall, clipped at 150, and 150 was chosen because it is the maximum initial horizontal offset at which circles are presented.

The agent's performance is evaluated under three different motor conditions. In the first condition, referred to as the *walking and wheels* condition, the agent must coordinate the behavior of both sets of effectors in order to catch the object. This condition can be thought of as the natural behaving state for the agent. In the second *walking only* condition, the agent's wheels effectors are lesioned, such that they have no effect on the agent's motion. In this case, the agent must catch circles using only its leg. Finally, in the third *wheels only* condition, the agent's leg is lesioned, and the agent must use only its wheel effectors to perform the task. Overall performance is then calculated by averaging trial performance for all 10 object offsets in each of the three motor conditions.

The agent's behavior is controlled by a continuous-time recurrent neural network (Beer, 1995b) with the following state equation:

$$\tau_i \dot{s}_i = -s_i + \sum_{j=1}^N w_{ji} \sigma(s_j + \theta_j) + I_i \quad i = 1, \dots, N$$

where  $s$  is the state of each neuron,  $\tau$  is the time constant,  $w_{ji}$  is the strength of the connection from the  $j^{th}$  to the  $i^{th}$  neuron,  $\theta$  is a bias term,  $\sigma(x) = \frac{1}{1+e^{-x}}$  is the standard logistic activation function, and  $I$  represents an external input. The output of a neuron is  $o_i = \sigma(s_i + \theta_i)$ . The agent's sensors are fully connected to a layer of seven interneurons, which are fully interconnected and which project fully to the five motor neurons. In addition, to cut down on the number

of parameters that need to be evolved, the agent's neural architecture is forced to be bilaterally symmetric.

Neural parameters are evolved using a real-valued genetic algorithm with rank based selection. A fitness scaling multiple of 1.01 and a mutation variance of 4 were used. The following parameters, with corresponding ranges, are evolved: time constants  $\in [1, 20]$ , biases  $\in [-16, 16]$ , and connection weights (from sensors to neurons and between neurons)  $\in [-16, 16]$ . Simulations are integrated using the Euler method with a step size of 0.1. In addition, in preliminary evolutionary runs it was discovered that, by evolving agents in all three motor conditions from random initial conditions, agents would converge prematurely to solutions that performed well in the wheels only condition but poorly in the other two conditions. Presumably this finding is due to the fact that walking is a much more difficult behavior to evolve than motion via pure force effectors, and so walking performance was unable to bootstrap itself before the wheels only condition had already been optimized. In order to overcome this difficulty, agents were evolved initially in the walking only condition until an average performance of 90% was reached, and only then were they evolved under all three motor conditions. On the order of 3,000 generations were required to reach an initial level of 90% proficiency in the walking only condition, and then agents were evolved for an additional 10,000 generations in all three motor conditions. A population size of 200 was used in all evolutionary runs.

## Behavioral Analysis

The best evolved agent achieved a mean performance of 97.1% on 5,000 evaluation trials with horizontal offsets uniformly distributed between  $[-150, +150]$  for each of the three motor conditions, with performances of 98.6% with wheels only, 96.5% with walking only, and 96.1% with walking and wheels. The performance of the best evolved agent is shown in Figure 3. From this, it is clear that the agent exhibits a high-performing and general solution to the task. Accordingly, the next question that we would like to ask is how this works. In particular, how does the agent utilize different patterns of feedback to produce the different behaviors? For that matter, how different are the behaviors to begin with? Does the agent's neural circuit use different autonomous dynamics to produce the different behaviors, or is the behavior truly a collective property of the entire brain-body-environment system? While some of these questions are beyond the scope of the present study, we can move towards answering them by performing a detailed analysis of the agent's behavior. By examining the agent's behavior and how it changes under various perturbations, we can begin to constrain the possible underlying mechanisms that might give rise to it.

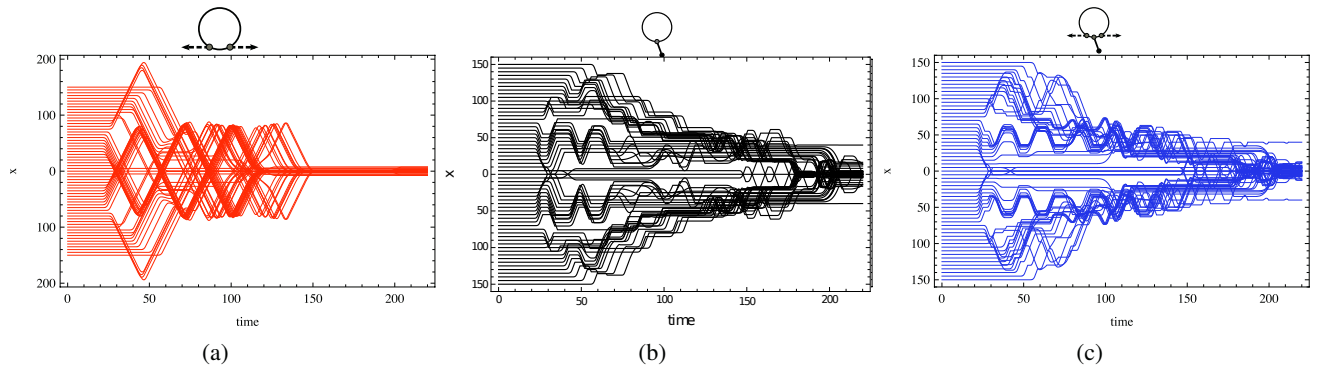

Figure 2: The agent's behavior. The agent's motion over time in object-centered coordinates is shown for the (a) wheels only, (b) walking only, and (c) walking and wheels conditions.

Figure 3: Generalization performance over initial horizontal position for the best-evolved agent. Performance is shown for the (a) wheels only, (b) walking only, and (c) walking and wheels conditions.

Figure 4: Behavioral comparison. Each plot shows the agent's behavior in the wheels only (red), walking only (yellow), and walking and wheels (blue) conditions when the same stimulus is presented.

## Normal behavior

We start by examining the agent's behavior under normal circumstances. This is shown in Figure 2, where sample trajectories of the agent's motion in each of the three motor conditions are shown. In the wheels only condition, the agent's behavior is characterized by large scans back and forth over the object, before ultimately centering the object as it reaches the bottom of its fall. Interestingly, for offsets

around 100 in the wheels only condition, the agent actually begins by moving further away from the object before turning back and centering it. The agent's motion in the walking only and walking and wheels condition show striking differences from the wheels only condition, largely due to the different biomechanics for walking versus wheels. Successful walking requires that the agent alternate between exerting force while the foot is down and swinging the leg back while the foot is up, resulting in a motion trajectory that al-

ternates between short bursts of motion and stasis. In contrast, with the wheels the agent is able to glide smoothly back and forth unimpeded. The plots in Figure 2 also show apparent similarities between the walking only and the walking and wheels conditions, giving an initial impression that behavior in these two conditions is more closely related than either is to the wheels only condition.

### Behavioral comparison

Next we can ask how much the agent's behavior actually differs in the three motor conditions. Since it is a basic supposition of this paper that the neural circuit exhibits *different* behaviors, this is an important question to ask. Here a clarification also must be made regarding the intended meaning of "behavior". At one level, the agent's behavior can be considered the same in all three conditions, since in each case the agent realizes the same high-level goal of catching circles. However, if behavior is defined at the lower level of the actual motor trajectories that are produced, then the behaviors may in fact be different in each case. That is, although the agent realizes the same goal in each condition, the actual motor actions required for walking versus wheels versus coordinating both may differ substantially. To determine whether this is the case, we can begin by comparing the agent's behavior in the three conditions when presented with the exact same stimuli (Figure 4). From this comparison, we see that, despite the apparent similarities between the walking only and walking and wheels conditions in Figure 2, the behavior in all three conditions is actually quite different. The contrast is most clear in Figure 4(c), where the trajectory for the walking and wheels condition can be seen to combine the steplike motion of the walking condition with periodic glides characteristic of the wheels only condition.

While Figure 4 provides an initial qualitative comparison of behavior in the three conditions, it is also possible to perform a more rigorous and quantitative comparison. To do this, we record the agent's motor outputs in one of the three conditions and then "playback" various of the motor streams to determine how the agent would have performed in the other conditions. For example, when the agent is evaluated in the wheels only condition, the agent actually produces motor outputs for the leg as well, but those outputs are simply ignored in order to simulate the leg being lesioned. Thus, if we record the outputs of the leg motors during the wheels only condition and then subsequently play them back, using them to drive the agent's leg effectors, we can examine how the agent would have performed had it been in the walking only condition. Similarly, we can play back the motor streams for both the wheels and leg to simulate the walking and wheels condition. In general, we can perform the same experiment by running the agent in each of the three conditions and performing playback simulations of the other two. The results from performing these experiments are shown in

Figure 5, both as average performances and as performance across the range of horizontal offsets. Clearly, there are significant drops in performance in all of the playback conditions. The largest drops are found between the wheels only condition and the other two, in line with our earlier observation that behavior is most different in the wheels only condition. However, even between the walking only and walking and wheels conditions there are significant declines in performance. Thus, the results of these experiments strongly support our earlier qualitative observations that the agent does in fact produce different behaviors in each of the three conditions.

### Effects of removing the object

Having established that the agent exhibits different behaviors, we can next ask about the source of this behavioral differentiation. In particular, to what extent does the differentiation rely on continuous feedback from the environment? If we found, for instance, that the agent does not rely on continuous feedback, this would suggest that the agent's neural circuit may be intrinsically multifunctional, with initial environmental input serving only to switch the agent into one or the other of its behavioral modes. On the other hand, if the different behaviors rely on continuous feedback, this would lend support to the idea that the environmental feedback is in fact crucial for producing the different behaviors. To determine which is the case, we can remove the visual object at different times during each trial and measure the impact on performance. Figure 6 shows the results of performing these experiments. Performance in all three conditions is significantly impaired by removing the object at nearly all times except very late in the trial, presumably after the agent has already settled on its final position. Also, interestingly, whereas the walking condition shows a steady increase in performance as the object is removed later in the trial, the other two conditions show much greater variability. There are certain times when the agent is very sensitive to the object being removed, and certain other times when performance is hardly affected at all. Also, by comparing the density plots in Figure 6 with the behavioral trajectories in Figure 2, one can begin to see why this is likely the case. The points in time when performance is impacted the most appear to correspond to times when the agent's behavioral trajectory is changing, turning either towards or away from the object. Thus, one reasonable prediction is that environmental feedback influences behavior precisely at these critical junctures, when the agent is actively moving to position itself with respect to the object.

### Effects of switching motor conditions

The final set of experiments examine the agent's ability to flexibly switch between the motor conditions. There are several reasons why the results of these experiments are of interest. First, the ability to switch between conditions provides a

measure of the robustness of the agent's control mechanism. Since, as is well established by now, the behavioral trajectories in each condition are actually quite different, it is not at all obvious that the agent should be able to switch behaviors mid-trial. Successful walking, for example, may rely fundamentally on the precise pattern of feedback that the agent selects for itself while walking, which differs significantly from feedback in the walking and wheels condition. Thus, to the extent that the agent is able to switch conditions, we can explore the robustness of the evolved mechanism. A second reason that these experiments are of interest is that the ability to switch behaviors would also provide further support for the idea that the agent's behavior relies fundamentally on continuous environmental feedback. For example, if the agent uses feedback only to switch into one or the other behavioral mode, and ignores it thereafter, then the agent presumably will fail when switched to a different condition. On the other hand, if the agent is continuously adjusting its behavior online as a result of changing patterns of feedback, then it is more likely able to adapt to a different motor condition.

The results of switching motor conditions at different times during the trial are shown in Figure 7. First, we see that when switching from the wheels only condition to either of the other two conditions performance decreases significantly, especially as the switch occurs later in the trial. One possible explanation for this is that the agent sweeps back and forth over the object much more widely in the wheels

only condition, and when switched to the walking only or walking and wheels condition it may be unable to recover this distance before the object completes its fall. However, when switching from either of the other two conditions, performance remains high regardless of when the switch occurs. This is a somewhat surprising result, especially considering switches to the wheels only condition which, as we have seen, involves very different behavior. Moreover, this result also provides strong support for the earlier findings of Section 3.3, indicating that the agent's behavior relies fundamentally on continuous environmental feedback.

## Discussion

Although neural mechanisms are undoubtedly crucial in producing different behaviors, the embodied and embedded contexts of neural circuits also provide many additional degrees of freedom that are often under-appreciated. Behavior is the product not of brains, but of entire brain-body-environment systems, and each of these three components may have a profound influence on behavior. This paper explored the ability of environmental feedback to drive the production of different behaviors from a single fixed neural circuit. Agents were evolved to accomplish the same objective—catch circles—under three different motor conditions, and based solely on the different patterns of environmental feedback produced by these conditions. The successful evolution of agents in this task demonstrated the ability of environmental feedback alone to drive behavioral selec-

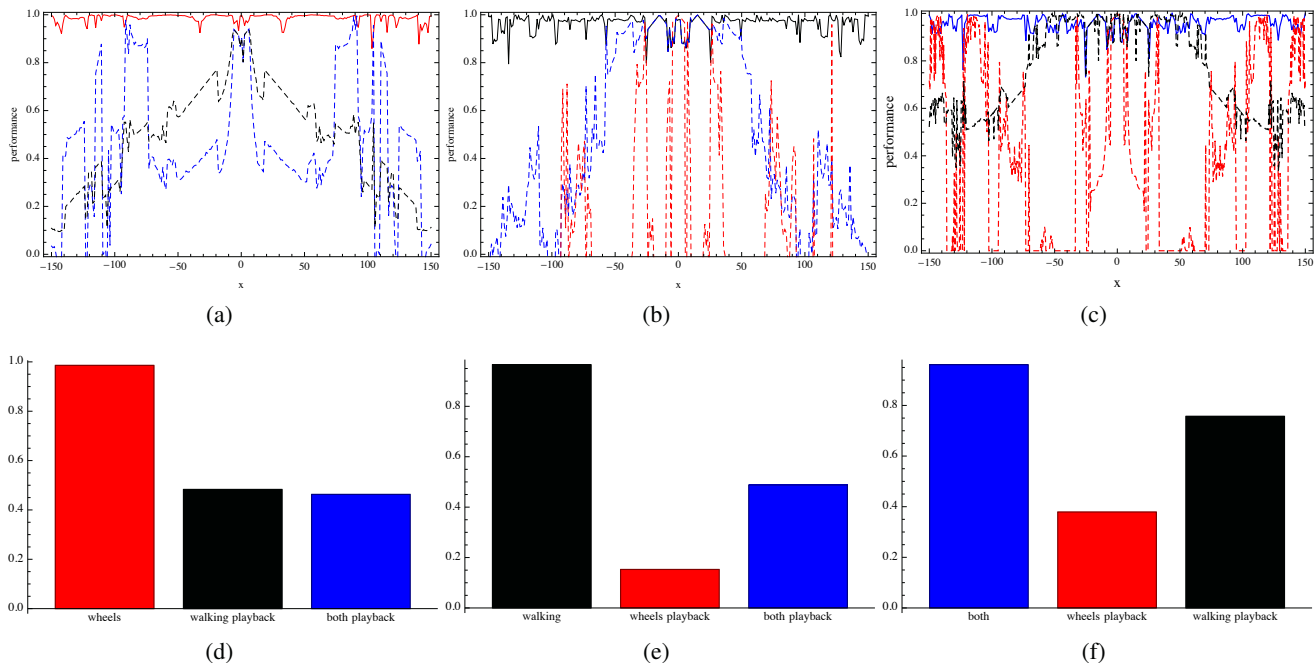

Figure 5: Playback performance. Plots (a)-(c) show the agent's normal performance (solid line) and playback performance (dashed lines) for the wheels only (red), walking only (yellow), and walking and wheels (blue) conditions. Average performances for the normal and playback conditions are shown in plots (d)-(f).

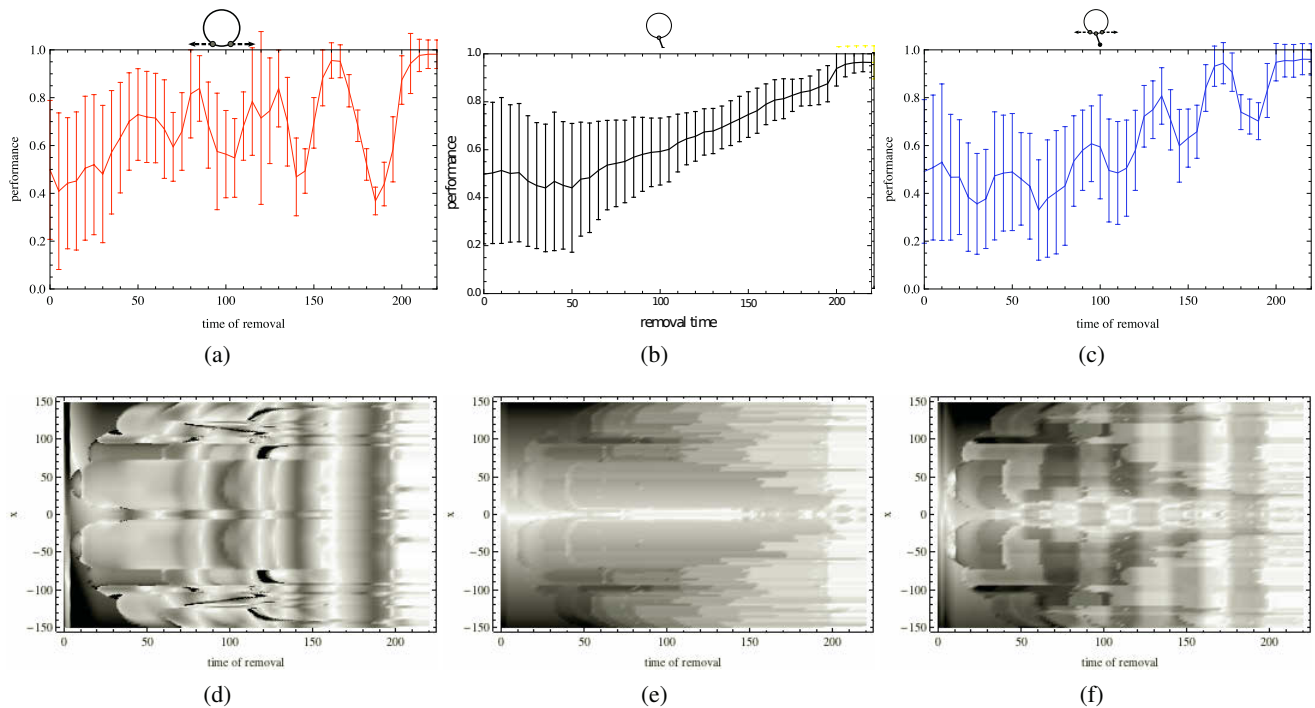

Figure 6: The effect of removing the object. The top row shows the agent’s average performance as a function of the time when the object is removed, averaged over horizontal positions of the object. The bottom row shows density plots of performance as a function of the object’s horizontal position and the time of removal.

tion. Next, a detailed analysis of the behavior of the best evolved agent was performed. Preliminary experiments provided quantitative evidence in support of the claim that the behaviors produced by the agent differ significantly. Next, experiments where the agent’s environmental feedback was removed at different times during each trial, by removing the object that the agent is supposed to catch, showed the agent’s fundamental reliance of continuous environmental feedback. Finally, experiments where the agent was switched between motor conditions at different times demonstrated the robust behavioral mechanism that the agent employs, and further confirmed the agent’s reliance on continuous environmental feedback.

### Abstract

Foraging bees often search in complex natural environments for "target" flowers that they have learnt provide nectar rewards. To maximise efficiency, bees must avoid landing on "distractor" flowers that do not offer rewards, as this potentially wastes time and energy. This paper reports on artificial-life inspired agent-based simulations of two contrasting approaches different bee species use to scan for targets in a scene containing many flowers. The two scanning approaches simulated are a parallel scan typical of bumblebees that is not slowed by distractors, and a serial scan typical of honeybees that is faster than parallel scan for single element processing, but is slowed by the presence of distractor flowers. The simulations were conducted over a range of target densities, and over a range of target/distractor ratios, to evaluate the types of environment in which each scan mechanism is most effective. Serial scan was found to be generally more effective in environments populated with a single type of rewarding species of flower, and parallel scan appears to be relatively more effective in environments populated with a mix of rewarding and unrewarding flowers. Our results support the hypothesis that environmental factors led to the evolution of different visual processing mechanisms in honeybees and bumblebees. This establishes a firm basis for psychophysical research exploring how and why the two different processing mechanisms may have evolved in these animals.

### Introduction and Previous Work

Foraging worker bees collect nutrition to sustain a beehive. Individual bees travel on "bouts" between their hive and flowers that may present nectar and pollen as nutritional rewards. Some bee species like honeybees (*Apis mellifera*) have colonies of foragers numbering in the thousands; while other species like bumblebees (*Bombus terrestris*) typically have less than 100 foragers (Frisch 1967, p.7; Duchateau and Velthuis 1988). Differences in search strategy between individual bees are amplified many times by the numerous bouts an individual travels during a day, many more times depending on the number of bees in a colony sharing that strategy, and more times still over a season or the life of a colony. The evolutionary relationship of different bee species and flowers is likely to have endured over many millions of years (Dyer, Boyd-Gerny *et al.* 2012), suggesting that selective pressure to evolve optimal solutions may exist in current day populations (e.g. examples throughout (Lythgoe

1979)). The search strategy employed should therefore be adapted to local environmental conditions, maximising the net flow of energy into the hive to enable survival and reproductive success of the queen bee. Costs associated with unnecessary workers, or excessive flight and flower handling should be avoided, but this is not straightforward in complex natural environments (Burns and Dyer 2008).

During a foraging bout, bees search for *target* flowers that they have learnt provide nectar rewards. Many social bees, like honeybees and bumblebees, exhibit flower constancy and tend to forage consistently from one type of rewarding flower as long as it continues to present rewards (Chittka, Thomson *et al.* 1999). However, in complex environments with many flowers, bees must avoid landing on unrewarding *distractor* flowers as this wastes time and energy (Burns and Dyer 2008). When the colours of target and distractor flowers are very different (e.g. blue and yellow as seen by humans), and there are only two flowers to choose between, bees can accurately assess the type of a flower presented to them (Giurfa 2004; Dyer, Spaethe *et al.* 2008). However, it isn't currently well understood how bees make decisions in complex environments containing many flowers of different types, colours, target/distractor ratios and arrangements. For instance, in tropical forests, single trees with thousands of simultaneously blooming rewarding flowers, potential targets, may appear (Fig. 1a), and distractor flowers are not intermingled among them (Clark 1994). However, in temperate environments, diverse carpets of small herbaceous plants may include a scattered few targets peppered among numerous distractor species (Fig. 1b), or a uniform carpet of a single species may occur that is many meters across depending upon location or season (Fig. 1c).

Apart from the obvious biological interest foraging raises (Pyke 1984), understanding bee foraging has many practical implications for agriculture where globally, crop bee-pollination is directly responsible for 35% of worldwide food production and is worth an estimated 153 billion Euro annually (Kjøl, Nielsen *et al.* 2011, pp.1-49). Bee pollination is also essential for natural ecosystem management (Hegland, Nielsen *et al.* 2009). It is therefore imperative that we understand how different bee species operate in different environments. This also provides insight into how potential

temporal or spatial mismatches in bee-pollinator and/or flower blooming may be affected by predicted changes in environmental conditions (*ibid.*). Furthermore, understanding bee visual attention mechanisms is relevant to artificial vision and search system design (Srinivasan 2011).

Figure 1: Sample flower distributions: (a) flowering tree, (b) patchy temperate carpet, (c) uniform temperate carpet.

**Biological background.** Following recent experiments with live free-flying bees, Morawetz and Spaethe (2012) propose that bumblebees (*Bombus terrestris*) conduct what appears to be a limited *parallel* style visual scan for targets that is not significantly slowed by increasing the number of distractors, while honeybees (*Apis mellifera*) use a *serial* styled scan that is faster for decisions where only targets are present, but is slowed considerably when distractors that must also be processed by the visual system are present. These different spatial attention mechanisms are potentially required to allow an organism with finite information processing capacity to handle the essentially infinite complexity of applying vision in natural environments (Treisman and Gelade 1980; Treisman and Gormican 1988; VanRullen, Carlson *et al.* 2007).

The study on free-flying honeybees and bumblebees (Morawetz and Spaethe 2012) used differently coloured paper

targets known to stimulate the trichromatic (UV, blue and green sensitive (Dyer, Paulk *et al.* 2011)) colour processing system of bees. This type of behavioral testing relies on the fact that individual bees can be trained to visit a target colour by associating a sucrose solution which the bees collect as nutrition, whilst the distractor stimuli offer no reward to bees who therefore avoid this colour. This scenario is biologically relevant since flowers may only offer rewards in certain temporal cycles, and there are some that mimic rewarding flowers and try to obtain pollination through deception (Dafni 1984; Dyer, Paulk *et al.* 2011). The Morawetz and Spaethe (2012) study was conducted in a controlled arena with stimuli presented at set visual angles. The number of targets and distractors was systematically varied. The results showed that increasing the number of distractors led to a significant increase in the decision-making time for honeybees, consistent with theories of a serial search mechanism (Treisman and Gelade 1980; Treisman and Gormican 1988; VanRullen, Carlson *et al.* 2007). However, in bumblebees a different processing system was observed. While decisions for finding a target with only a single distractor were about 1.5 times as long as for honeybees, increasing the number of distractors did not significantly affect the decision-making time of bumblebees. This type of decision-making is consistent with a parallel visual search (*ibid.*). In the current study we use simulations to test the implications on nectar gathering effectiveness, as a biologically relevant measure of fitness, for parallel and serial scanning mechanisms.

**Simulation background.** Experiments with free-flying bees require marking and tracking individual animals moving freely in 3D space, making it difficult to collect sufficient reliable data to answer iterative questions about optimal mechanisms in multiple environments. Hence, we employ an agent-based model (ABM, or individual-based model, IBM) simulating parallel and serial scanning bees in different environments. Our artificial bees (a-bees) search a grid world populated by target and distractor flowers. We systematically sweep through a biologically relevant range of target densities and target/distractor relative abundances, aiming to determine the environmental floral distributions in which each visual scan mechanism is likely to be effective in real world scenarios. The simulations allow us to interpret the factors that influence how and why bees make decisions, and the subsequent colony-level benefits that may act as biologically relevant factors for reproductive success (Burns 2005; Burns and Dyer 2008).

Where bee behaviour varies between individuals or where local environmental conditions influence individual decision-making, ABMs offer a powerful approach for understanding the intricate interactions and emergent outcomes of these complex systems (Huston, DeAngelis *et al.* 1988; Judson 1994; Grimm 1999; DeAngelis and Mooij 2005; Grimm and Railsback 2005; Grimm, Revilla *et al.* 2005; Dorin, Korb *et al.* 2008). ABMs have been used to model bee behaviour since the 1980s (Hogeweg and Hesper 1983). For example, they have been used to understand bee foraging strategies in keeping with empirical data whilst considering recruitment,

homing and memory of food source location (Vries and Biesmeijer 1998); and to show that the benefits of recruitment by honeybees is dependent on the density of flowers within certain environments (Dornhaus, Klügl *et al.* 2006). ABMs have also been applied to understand the impact of flower constancy under conditions where flower rewards become available or unavailable cyclically (Dyer, Dorin *et al.* 2012).

In this current study we use ABMs to understand the potential colony level benefits of the empirically determined visual scanning behaviour discovered in honeybees and bumblebees. Specifically, we hypothesise that if environmental conditions like flower density have been a factor in the evolution of different bee species' visual search mechanisms (Dyer, Spaethe *et al.* 2008; Morawetz and Spaethe 2012), then there should be evidence of biologically plausible flower distributions best suited to foraging by bees employing the different mechanisms.

## Simulation Method

The ABM we have designed simulates the components pertinent to testing the hypothesis just stated, while eliminating irrelevant factors – KISS.<sup>1</sup> In detailing the simulation here we discuss aspects of real bee behavior included or excluded to test our hypotheses. The system was implemented entirely in the C programming language but there is nothing in our model that could not be built in any other similar language by following the description below.

### Artificial-Bees (A-Bees)

Bees are central place feeders that leave their hive to search for nutrition. We model bees as software agents, a-bees, foraging within a virtual bounded foraging patch. The patch is uniformly divided into square grid cells. At most one virtual flower can occupy a grid cell. An a-bee also occupies a single grid cell with or without a flower. In this section we detail a-bee behaviour, the simulated environment and the relationship of these aspects of our model to reality.

We model bee colonies of 60 foragers. The exact number is not critical since we eliminate inter-agent communication and population density effects by ensuring that, in essence, each a-bee exists in a world of its own. Inter-agent effects are complicating factors that would change the viability of different visual scan mechanisms for hives of different size and under different environmental conditions. In keeping with KISS described above, the simulation eliminates these to reduce one key problem to its basic form.

Honeybees have evolved a complex language for communicating target whereabouts to one another (Frisch 1967, pp.321-328). This is of particular benefit in environments where targets appear in large clusters (Dornhaus, Klügl *et al.* 2006). This communication system is likely to impact on the effectiveness of different bee species'

visual scanning techniques, but we have avoided introducing it here in order to establish a baseline for comparing only the visual scans of honeybees against those of bumblebees (Dornhaus and Chittka 1999).

Bees can use vision and olfaction to help find flowers; e.g. (Streinzer, Paulus *et al.* 2009). Our model only considers visual scan. Our a-bees can distinguish between targets and distractors with 100% accuracy. This is biologically plausible for saliently different colours (Giurfa 2004; Dyer, Paulk *et al.* 2011).

Bee spatial acuity is relatively poor compared to human vision, and in real life bumblebees can only detect a plant's cluster of 3-5 flowers (each flower of 2.5cm diameter) at a distance of approximately 0.7m (Dyer, Spaethe *et al.* 2008; Wertlen, Niggebrugge *et al.* 2008). Detection appears to approximate a step function, so we model it as distances >0.7m — not detected, distance <0.7m — 100% chance of detecting a flower that is present. Our foraging patch model is based on a grid world of square cells of dimension 0.35m, so an a-bee can see flowers in its Moore neighbourhood (8+1 cells, n=1), but no further.

An individual a-bee keeps track of the flowers it has visited and will not visit a flower twice in a single foraging simulation. This is biologically plausible and the ability is an important aspect of bee foraging behavior (Giurfa, Núñez *et al.* 1994). An a-bee will move into a grid cell towards a target if it has not visited that target before. It will then visit that target (to collect the modeled nutritional reward), taking a parameterised amount of time, *VisitTime*. Real bees do have a central foveal region in which they may see detail better. However its operation in complex environments for different species has been poorly studied (but see (Morawetz and Spaethe 2012)). For simplicity we eliminated this factor here; a-bees are not directionally biased in their visual scan.<sup>2</sup> We model the two bee scan mechanisms as follows.

**Parallel scan.** An a-bee using a parallel scan (Fig. 2) processes all of the information it sees about flower locations in its visible range simultaneously. This process takes the "parallel a-bee" a constant amount of time, *ParallelTime*, regardless of how many flowers it can see and regardless of whether these are distractors or targets. It is as if in *ParallelTime* the bee forms a mental image of the whole visible scene and recognises the closest target, while ignoring all non-targets.

A parallel a-bee will move towards an unvisited target it sees that is drawn from a uniform random distribution of available target flowers. If it finds no target, or no flowers at all, it will conduct a random walk as discussed shortly.

<sup>2</sup> However, we did test the impact of bias in the a-bees' preferred direction of travel (below).

<sup>1</sup> Keep It Simple, Stupid (Axelrod 2003).

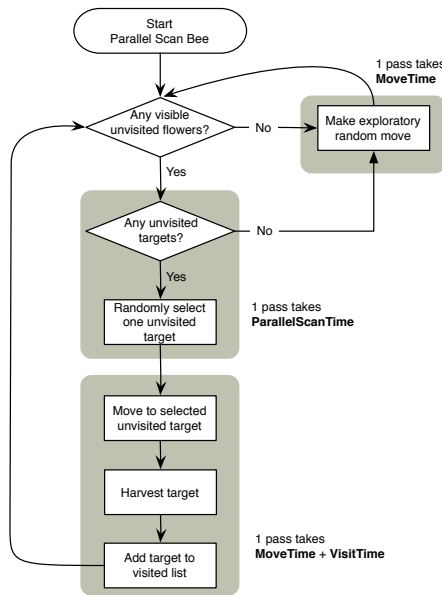

Figure 2: The foraging cycle of a parallel visual scan a-bee.

**Serial scan.** An a-bee using a serial scan (Fig. 3) examines one flower in its visible region at a time, selecting flowers to investigate from a uniform random distribution across available flowers. It takes this “serial a-bee” the parameter value *SerialTime* to examine *each* flower, until it finds a target, or until it has examined all the flowers it can see and finds no targets. A serial a-bee always moves towards the first unvisited target it sees in its scan. It stops scanning as soon as it finds an unvisited target. In the absence of unvisited targets or any flowers at all, the serial a-bee conducts a random walk as discussed below.

**A-bee movement.** As long as all a-bees, regardless of parallel/serial visual scanning mechanism, apply the same movement strategies, we can assess the *relative* benefits of the scanning mechanisms free from interference introduced by movement strategies that are themselves complex and worth independent study (Waddington 1980). Hence it is especially important here to eliminate unnecessary complications from the simulation. Since we are concerned with bee decision-making times and unconcerned about bee travel times, we don’t require a-bees to return to a hive and therefore don’t model one. A-bees do not run out of nectar storage; they accrue it indefinitely during a simulation run.

In parameter *MoveTime* simulation time-steps an a-bee can move into any cell in its Moore neighbourhood, or choose to remain in its current cell. But in which direction should it head? If it sees a target flower, as discussed above, it will move towards that. In the absence of target flowers, a-bees conduct either a random walk or a *biased* random walk around their Moore neighbourhood depending on the experiment.

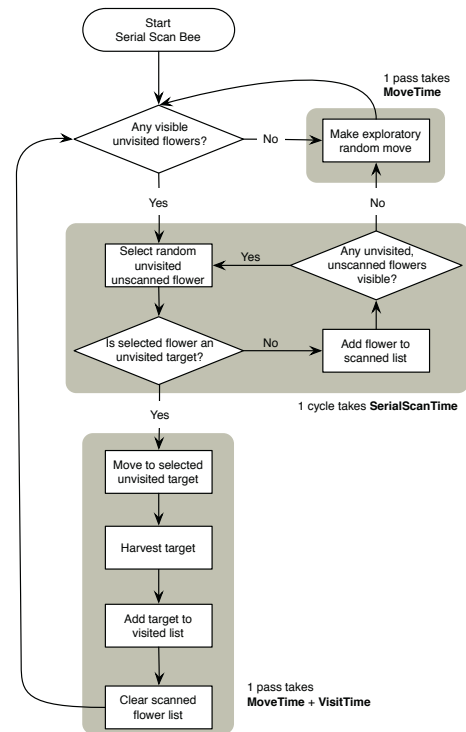

Figure 3: The foraging cycle of a serial visual scan a-bee.

While an ordinary random walk between grid cells is not a biologically realistic foraging strategy, it provides a convenient baseline against which we compare the impact of a *biased* random walk derived from a study of real bees’ directional preferences (Waddington 1980, Fig. 1). The probability of a biased random walking a-bee selecting a specific cell from its Moore neighbours in the absence of suitable target flowers is given in Fig. 4. As can be seen, it prefers to continue straight ahead, but is not completely averse to changing direction. We investigated these two navigational strategies to determine if they had any impact on the relative success of the visual scan techniques.

Figure 4: Probability of movement relative to (example) current headings of an a-bee following a biased random walk. Values calculated from (Waddington 1980, Fig. 1).

### Artificial Foraging Environments

A colony’s foraging environment is modeled as a bounded world of  $571 \times 571$  square grid cells. Cells represent  $0.35\text{m}^2$ . Hence, the simulated foraging site is 200m across.

Target flowers offer a reward of 1 unit to every a-bee that visits them. Distractor flowers offer no reward.<sup>3</sup> Flowers are distributed differently across the patch depending on the experiment, as described in the next section.

## Experiments

We conducted experiments to determine the impact of various flower distributions on the relative success of colonies composed either entirely of parallel a-bees, or entirely of serial a-bees. The simulation parameters described below are summarised in Table 1.

**Target-only experiments.** In some environments, bees only encounter a single flowering species during a foraging bout (Fig. 1a & 1c). This is often the case under tropical conditions where massive flowering trees can be encountered, or in homogeneous agricultural fields. In experiments conducted to model these conditions, colonies of serial and parallel a-bees foraged in patches containing only targets. The number of target flowers in the patch was increased systematically to occupy from 0% to 100% of the grid cells. Serial and parallel visual scanning mechanisms were compared at each density. Flower positions were distributed uniform randomly across the patch in each case. These experiments were primarily used to inform the choice of target density to be used in the *Target and distractor experiments* described next.

**Target and distractor experiments.** In order to ascertain the relative impact of distractor flowers on the serial and parallel visual scanning mechanisms, distractors were placed in the foraging patch among a fixed number of targets. In our simulation, distractor flowers form a single class of non-target flower. In the wild there may be many species of distractor. However, our simulation remains biologically relevant since, as detailed in section Biological background, when distractor flowers are of saliently different colour to targets, bees reliably distinguish between them.

For the Target and distractor experiments, the density of target flowers in our simulated patch was fixed at 10% of the grid cells. There were three reasons for this density choice:

- (i) Since we are measuring the relative success of the two visual scanning mechanisms by recording the total number of reward units gathered during the simulations, we always require some target flowers for a-bees to harvest.
- (ii) To maximise our ability to distinguish differences between visual scan mechanisms we need to provide sufficient targets that foraging a-bees do not exhaust the supply of unvisited targets during a simulation run.
- (iii) We need to sweep across a wide range of distractor flower densities. By fixing targets at 10% we have from 0% up to the remaining 90% of grid cells to populate with distractors.

<sup>3</sup> Actually, a-bees never visit distractors as they distinguish flower types with 100% accuracy. This is consistent with empirical data for bees visiting saliently different coloured flowers (Giurfa 2004).

Our Target-only experiment results demonstrated that 10% target density met all three requirements. These results are described below. Hence, during Target and distractor experiments, the number of distractors in the patch was increased systematically to occupy from 0% to 90% of the grid cells. The two visual scanning mechanisms were tested at each distractor density. Flowers were distributed uniform randomly across the patch in each case, simulating a temperate environment with different numbers of distractors positioned among targets (Fig. 1b).

Environment	
Patch size	571 × 571 cells, bounded
Patch grid cell size	0.35 × 0.35m
Colony size	60 parallel, or 60 serial scan a-bees
A-bees	
Flower presence detection accuracy	100% from neighbouring cell or cell shared with a flower
Flower type recognition accuracy	100% from neighbouring cell or cell shared with a flower
Storage capacity	Infinite
Visited flower memory length	Every flower visited in a simulation run
Flower visit ( <i>VisitTime</i> )	1 simulation time step
Complete field of view parallel scan ( <i>ParallelTime</i> )	3 simulation time steps
Single serial scan flower examination ( <i>SerialTime</i> )	2 simulation time steps
Movement in Moore neighbourhood ( <i>MoveTime</i> )	1 simulation time step
Simulation	
Duration	1000 simulation time steps
Number of runs	20 per data point

Table 1: Main simulation parameters.

## Simulation verification

We tested that the simulation behaved according to the specifications above. Tests included that a-bees were:

- Correctly following their respective visual scanning mechanisms in assessing visible flowers;
- Remembering visited target flowers;
- Not exhausting the global target flower supply;
- Not exhausting the local target flower supply.

Where possible we also compared analytically derived values to simulation results. To ensure our a-bees' simplistic random walk navigation strategy did not influence the *relative* success of the tested scanning mechanisms, we compared the results of this navigation strategy against a more plausible biased walk derived from empirical data. See the Results for a discussion of these experiments.

## Results

### Target only experiments

In these experiments the foraging patch was filled purely with target flowers. The number of target flowers was increased systematically from 10% to 100% of the grid cells in the patch. The effects of this increase on the amount of nectar collected are shown for colonies of parallel and serial a-bees (Fig. 5). All bees in these experiments executed an ordinary random walk.

At target densities of 1 or 2 % there was a relatively low rate of nectar collection by a-bees with either serial or parallel search mechanisms (Fig. 5). A comparison of nectar collection success for colonies of a-bees using parallel (mean  $4920 \pm 103$  units) or serial (mean  $5323 \pm 118$  units) visual search considering 10% target density and no distractors was conducted with a non-parametric Mann-Whitney U test (SPSS v15.0: IBM, Chicago, USA) for 2-independent groups of  $N=20$  runs/group ( $Z=-5.383$ ,  $p<0.001$ ). Thus at 10% target density, a-bees with a serial search mechanism collected significantly more nutrition. As target flower density increases in the presence of no distractors, the serial search becomes increasingly more effective than the parallel search mechanism (Fig. 5).

Figure 5: Graph of nectar rewards collected by colonies of a-bees versus the percentage of grid cells occupied by target flowers. Data points are the mean of 20 simulations; error bars  $\pm 1$  std. dev.

### Target and distractor experiments

In these experiments 10% of the foraging patch was randomly filled with targets. Distractor density was increased systematically from 0% to 90% of the total number of grid squares. The distractors were randomly distributed among the cells unoccupied by targets. The effects of this increase on the amount of nectar collected by colonies of parallel and serial a-bees executing ordinary random walks and biased random walks are shown (Fig. 6).

Considering first the a-bees executing an ordinary random walk. For distractor densities less than 1%, the serial scan mechanism outperforms the parallel scan (see Fig. 5 above,

since the Target only experiment at 0% distractors, matches the experiment here at 0% distractors). However, parallel scan takes over as the most efficient mechanism at higher distractor densities, even where the number of distractors is much less than the number of targets. Parallel scan is clearly more efficient than the serial scan as distractor flower density increases beyond target density.

The trends for a-bees conducting a biased random walk correspond directly to those for a-bees conducting an ordinary random walk, but with greater overall success for the former over the latter. The directional bias appears to enhance the speed with which a-bees' locate unvisited targets. It does this in equal proportion for a-bees using parallel or serial visual scan and didn't change the relative success of these mechanisms.

Figure 6: Graph of nectar rewards collected by colonies of a-bees versus the percentage of grid cells occupied by distractor flowers. Target flower density was fixed at 10%. Data points are the mean of 20 simulations; error bars  $\pm 1$  std. dev.

## Discussion, Conclusions and Future Work

In the current study we tested for the relative success of a serial scan as occurs in honeybees, and a parallel scan typical of bumblebees, considering previous evidence that honeybees evolved to forage in more tropical environments and bumblebees in temperate environments (Clark 1994; Dornhaus and Chittka 2004; Heinrich 2004; Dyer, Spaethe *et al.* 2008). This lead us to hypothesise that honeybees' serial scan may be more effective in environments where targets were not interspersed among distractors, and that bumblebees' parallel scan would be relatively more effective for foraging in heterogeneous environments where distractors and targets were intermingled. These hypotheses were supported by our simulation results as follows.

### Target only experiments

The ratio of nectar collected by the parallel a-bees to that collected by the serial a-bees in an environment without distractors approaches  $11,336:14,163 = 4:5$ . The serial mechanism is increasingly superior as target density increases.

This ratio can be derived analytically in the absence of distractors and a neighbourhood increasingly saturated with targets. For each traversal of the procedure in Fig. 2 a parallel a-bee requires  $ParallelTime + MoveTime + VisitTime$  to collect a reward unit. With our parameters (Tab. 1) this amounts to  $3+1+1 = 5$  simulation time steps. A serial a-bee's traversal of the procedure in Fig. 3 requires  $SerialTime + MoveTime + VisitTime = 2+1+1 = 4$  simulation time steps to collect a reward unit. Hence, a serial a-bee takes  $4/5^{th}$  the time of a parallel a-bee to collect a reward unit in this scenario.

We could have set our simulation parameters so that the a-bees' decision time wasn't the most time-consuming activity in its foraging cycle. This would potentially be more biologically plausible given that decision times as measured by Morawetz and Spaethe (2012) were generally less than 1.5 seconds (bumblebees) and 1.2 seconds (honeybees), and that the sum of travel and flower handling times may exceed these values in the real world by many seconds (Chittka, Gumbert *et al.* 1997; Chittka 2002). However, these time handling factors may also be complicated by interactions with other foraging insects in complex and competitive environments where being faster may allow the collection of rewards before competitors diminish resources (Burns and Dyer 2008). The impact of travel and flower handling times for real honeybees and bumblebees may impact on their relative success in different environments since each species may conceivably have differences in flight speed and flower handling skill under various real world conditions. But the scope of our experiments was only to test differences between the scanning mechanisms these species have been shown to employ. Hence, we neutralise flower handling and travel time differences by assigning equal values to *VisitTime* and *MoveTime* parameters for the two a-bee species.

It was found that real bumblebees reduce their decision time slightly, by a statistically significant amount, as the number of visible targets increases from one to four (Morawetz and Spaethe 2012). Hence, the gap we report between parallel and serial mechanisms may be decreased slightly from that shown for our a-bees as target density increases (Fig. 5).

### Target and distractor experiments

A distractor density of only 1% is sufficient to level the effectiveness of the serial and parallel scanning mechanisms. Any increase beyond this improves the parallel scanning mechanism's superiority over the serial scan. This is interesting as it implies that in many biologically plausible scenarios, parallel search would be the more efficient approach for collecting nutrition from rewarding flowers whilst avoiding dissimilar colored distractors. Why then mightn't honeybees have evolved a more efficient visual scan? A potential answer is provided in figure 5 where, in an environment with no distractors (as would be present in many tropical scenarios where large trees flower) fast serial search is more effective. Indeed, in studies that have compared the efficiency of honeybees at collecting nutrition in temperate and tropical environments, and where the capacity of the

honeybees to recruit nest mates to share in resource gathering was experimentally manipulated, research has found honeybees to be most effective in tropical environments (Dornhaus and Chittka 2004). Thus our current findings that there are biologically plausible conditions that best suit either a parallel or serial search mechanism, adds weight to the possibility of environmental conditions leading to the evolution of different visual capabilities in different bee species (Dyer, Spaethe *et al.* 2008; Morawetz and Spaethe 2012).

As noted above, the biased random walk has no impact on the relative success of the scanning mechanisms. However in absolute terms, in our simulations, the turning bias we implemented improved the parallel a-bees' foraging success by 20.48% (std. dev. 0.85) and the serial a-bees' success by 24.7% (std. dev. 2.4). This certainly leaves it open for those interested in optimal foraging to simulate more biologically plausible navigation schemes, however this was outside the scope of our study.

### Future work

Our findings suggest it would be valuable to compare tropical and temperate floral distributions and how these may have affected the processing capabilities of different bee species. This work is potentially useful because it has been suggested that climate change may lead to either spatial or temporal mismatches in the availability of flower resources and pollinators (Hegland, Nielsen *et al.* 2009), and indeed such mismatches could be influenced by the visual capacities of bees. Currently this is unknown, and testing bee species of high pollination value with flowers of different patchiness may provide important insights for future resource management.

# Using MapReduce Streaming for Distributed Life Simulation on the Cloud

Atanas Radenski

Chapman University, Orange, California  
Radenski@chapman.edu

## Abstract

Distributed software simulations are indispensable in the study of large-scale life models but often require the use of technically complex lower-level distributed computing frameworks, such as MPI. We propose to overcome the complexity challenge by applying the emerging MapReduce (MR) model to distributed life simulations and by running such simulations on the cloud. Technically, we design optimized MR streaming algorithms for discrete and continuous versions of Conway's *life* according to a general MR streaming pattern. We chose *life* because it is simple enough as a testbed for MR's applicability to a-life simulations and general enough to make our results applicable to various lattice-based a-life models. We implement and empirically evaluate our algorithms' performance on Amazon's Elastic MR cloud. Our experiments demonstrate that a single MR optimization technique called strip partitioning can reduce the execution time of continuous *life* simulations by 64%. To the best of our knowledge, we are the first to propose and evaluate MR streaming algorithms for lattice-based simulations. Our algorithms can serve as prototypes in the development of novel MR simulation algorithms for large-scale lattice-based a-life models<sup>1</sup>.

## Introduction

A-life has long relied on software simulations of the behavioral characteristics of living systems to facilitate the discovery of natural laws. Living systems involve vast numbers of evolving objects, and their software simulations can be data and computationally intensive. Large-scale life models may not fit in the memory of an average workstation, a challenge that can be overcome with the development of distributed a-life software. Distributed scientific simulations are usually implemented by using low-level libraries, such as MPI, which are difficult to program and require the development of custom fault-tolerance and load-balancing schemes --- a major challenge for scientists. Compute clusters to run distributed simulations can be expensive to build and complex to maintain. We believe that the complexity challenges of distributed life simulations can be overcome by applying the emerging higher-level MapReduce (MR) model to life simulations and by running such simulations on the cloud.

MR was initially developed to specifically satisfy Google's needs for large-scale distributed processing of unstructured

text data [Dean and Ghemawat, 2008]. The subsequent implementation of MR within Apache's open-source Hadoop framework [White, 2012] stimulated the development of wide range of MR applications in diverse areas, including sets and graphs; AI, machine learning and data mining; bioinformatics; image and video; evolutionary computing; and statistics and numerical mathematics [Radenski and Norris, 2013]. MR users develop serial code that is automatically executed in parallel by the MR engine in a fault-tolerant and load-balanced manner. The simplicity of the MR model and the built-in fault tolerance and load-balancing functionality of the MR engine can be beneficial in the development of data-intensive distributed scientific applications in general and life software simulations in particular.

Our general goal in this paper is to investigate the applicability of the MR model to large-scale distributed a-life simulations. To do so, we focus on life models that are based on cellular automata (CA) because CA are relatively easy to parallelize and have been used in life modeling and simulation from the early days of a-life. Indeed, a-life and cellular automata share a closely tied history which began with the CA works of John von Neumann [Von Neumann and Burks, 1966] and continued with the development and exploration of the game of life --- or simply *life* --- by John Conway [Gardner, 1970; Bays, 2010]. Conway's *life* is a 2D CA with two states (alive/dead). A popular *life* variation adopts a nondiscrete representation with states that are continuously valued between zero and one [Peper et al., 2010]. We use the terms *discrete life* and *continuous life* correspondingly to distinguish between the two *life* models.

CA has been recognized as historically the most fundamental paradigm of a-life [Conti, 2008], and *life* has become known as the prototypical CA [Hoekstra et al., 2010]. Hence, we consider *life* to be a most suitable candidate for this first study of the applicability of the MR model to large-scale distributed life simulations. Technically, we develop and empirically evaluate MR *life* algorithms for the discrete and continuous *life* models. We also discuss how our algorithms can be transformed into algorithms for other versions of *life*, such as 3D *life* and *life* with larger neighborhoods. We outline a general MR streaming pattern that encapsulates the common general features of the *D-Life* and *C-Life* algorithms and can be followed for the design of other lattice-based simulation algorithms in the MR streaming model. Our algorithms are by no means limited to *life* and can be used as prototypes for developing large-scale MR simulation algorithms for other CA-based life models.

<sup>1</sup> This work was performed by Atanas Radenski as a guest faculty at Argonne National Laboratory in Illinois while on a sabbatical leave from Chapman University, California in spring 2013.

Cloud computing is the use of hardware and software as service --- remotely, on-demand, and on a pay-per-use basis. Cloud computing can be viewed as a descendant of the well-established grid computing, enhanced with instant provisioning and utility computing. Elastic MR is one of the services provided by the Amazon's cloud computing platform, Amazon Web Services (AWS). Elastic MR is in fact Apache Hadoop hosted on AWS's Elastic Compute Cloud. We develop MR *life* algorithms in the Hadoop version of the MR model and then host the algorithms' execution on Elastic MR for the purpose of empirical performance evaluation. With AWS, we can launch various Elastic MR clusters as they are needed for our cost-effective experiments. We choose AWS because it is the first and currently the largest publicly available cloud computing platform.

Previously unknown complex self-organizing behavior of life models can be discovered by simulating vast numbers of generations for very large-scale model configurations. Such large-scale simulations may not fit on individual workstations but can be conveniently implemented in MR and executed on the cloud in a cost-effective, pay-per-use fashion. Our MR *life* algorithms and their empirical performance evaluation are intended to enhance scientists' understanding of the potential of MR and cloud computing in a-life research and open new opportunities for distributed large-scale life simulations.

The rest of this paper contains three sections. The first section describes how *life* simulations can be represented in the MR model. The second section discusses related work. The third section presents conclusions and possibilities for future work.

## Placing Life on MapReduce

This section introduces selected features of the MR model, defines MR algorithms for discrete *life* and for continuous *life*, offers a general MR streaming pattern, and ends with an empirical evaluation of the MR algorithms on the cloud.

### MapReduce Models and Frameworks

**Standard MR model.** In the *standard MR model*, user-defined serial *Map* and *Reduce* methods transform in parallel an input set of key-value (KV) pairs into an output set of KV-pairs. Initially, *Map* is applied in parallel to individual KV-pairs from the input set to produce a first intermediate set of KV-pairs.

$$Inter1 = \{(k2, v2)\} = \{Map(k1, v1) \mid (k1, v1) \in Input\}$$

This set of KV-pairs is then automatically transformed by MR into a second intermediate set of KV-pairs in which all intermediate pairs with the same key are sorted and grouped together, creating a single KV-pair for each intermediate key.

$$Inter2 = \{(k2, list(v2))\} = MR-Sort-and-Group(Inter1)$$

*Reduce* then is applied in parallel to individual KV-pairs from the second intermediate set to produce an output set of KV-pairs.

$$Output = \{(k3, v3)\} = \{Reduce(k2, list(v2)) \mid (k2, list(v2)) \in Inter2\}$$

Input, intermediate, and output keys and values may or may not belong to different domains.

Consider for example the problem of counting word frequencies in a text document. In standard MR word count, input KV pairs represent document's lines (Table 1). The standard MR engine parses the input keys and values and provides them as ready-to-use KV arguments to *Map* and *Reduce*. *Map* method invocations (Figure 1) parse individual lines (automatically submitted to *Map* through the *value* parameter) and produce the first intermediate set of KV pairs, where individual words serve as keys and 1s serve as values (Table 1). MR then automatically sorts and groups the first intermediate set into a second intermediate set (Table 1). Finally, *Reduce* method invocations (Figure 1) sumup grouped values to output the final count for each word (Table 1). Note that this particular *Map* method ignores all input keys. For practical convenience, MR frameworks automatically generate some default keys for existing text documents.

```

Figure 1: Word count in the standard MR model

**MR frameworks.** The MR model has been implemented in three principal types of frameworks: distributed MR (targeted at clusters of workstations) [Dean and Ghemawat, 2008], shared-memory MR (targeted at multicore, multiprocessors workstations) [Talbot et al., 2011], and GPU MR [He et al., 2008]. Distributed MR frameworks are the most popular in practical computing. Any distributed MR framework incorporates an MR engine and a distributed file system (DFS) to hold the input, intermediate, and output datasets.

Google was the first to develop a proprietary distributed MR framework, which has been available and used only internally [Dean and Ghemawat, 2008]. The popularity of the MR model grew significantly with the release by Apache of the open-source Hadoop framework [White, 2012], which extended the standard MR model with additional functionality, such as *MR streaming*. Hadoop is now the defacto standard MR framework, and we therefore target our distributed MR *life* algorithms to Hadoop (see [Lee et al., 2012] for advantages and pitfalls of Hadoop MR). For the rest

of this paper we omit “Hadoop” in references to the Hadoop MR.

The MR engine invokes *Map* and *Reduce* methods within persistent tasks that are distributed over the Hadoop cluster; we refer to such persistent tasks as *mappers* and *reducers*. The MR engine uses intermediate keys to partition all intermediate KV-pairs among available reducers and to sort all KV-pairs that are fed into the same reducer. Hence, all intermediate KV-pairs with the same key are submitted to the same reducer in sorted order, although the same reducer can be assigned to handle several different keys [Radenski, 2012].

The MR framework is implemented in Java, and standard MR algorithms target the MR Java API, thus requiring significant Java expertise. In contrast to standard MR, MR streaming algorithms target higher-level languages such as Python. Because MR streaming is easier to understand and modify by domain scientists, who may not be Java experts but can work well with Python, we chose to develop MR streaming algorithms for distributed *life* simulations. Such MR streaming algorithms can be straightforwardly implemented in Python. If needed, MR streaming algorithms can be transformed into equivalent standard MR algorithms.

**MR streaming model.** In an essential departure from the standard MR semantics, MR streaming sorts but does not group intermediate same-key KV-pairs at all, and the *Reduce* method must handle multiple occurrences of the same key with corresponding partial values (rather than a single list of grouped values as in standard MR). The semantics of the *MR streaming model* can be specified as follows.

$$\begin{aligned} Inter1 &= \{(k2, v2)\} = \cup \{Map(\{(k1, v1)\}) \mid \{(k1, v1)\} \subseteq Input\} \\ Inter2 &= \{(k2, v2)\} = MR\text{-}Sort(Inter1) \\ Output &= \{(k3, v3)\} = \cup \{Reduce(\{(k2, v2)\}) \mid \{(k2, v2)\} \subseteq Inter2\} \end{aligned}$$

While the standard MR engine parses data sets’ keys and values and provides them as ready-to-use KV arguments to *Map* and *Reduce*, the streaming MR engine provides all data via the standard input stream. Consequently, *Map* and *Reduce* must parse the input into keys and values on their own. Parsing input in a higher-level language is not necessarily a disadvantage of MR streaming: such parsing can be more straightforward and flexible than using the relatively complicated and rigid Java API to manage the input format in standard MR [Radenski and Norris, 2013].

In MR streaming word count, document’s lines are viewed as input KV pairs represent with empty keys (Table 2). The *Map* method (Figure 2) parses individual lines and produces an intermediate set of KV pairs in which individual words serve as keys (Table 2). MR then automatically sorts the first intermediate set into a second intermediate set (Table 2). Finally, the *Reduce* method (Figure 2) uses a loop to sumup sorted values then outputs the final count for each word (Table 2).

The distributed execution of mappers and reducers forms a single MR streaming job (Figure 3). Several MR jobs can be iterated so that the output from one job is used as the input for the next one. All input datasets, intermediate datasets, and output datasets for MR jobs are stored in the DFS. Iterative MR processing can be achieved by using functionality that is

external to the MR model or by using non-standard extensions of the MR model itself.

### Discrete Life in MapReduce

*Discrete life* is a CA with two states (dead/alive) over an infinite 2D lattice that evolves according the 2,3/2 rule: An alive cell with 2 or 3 alive neighbors in its Moore neighborhood stays alive, and a dead cell with 2 alive neighbors becomes alive. (As defined earlier, *discrete life* is our term for Conway’s *life*, as opposed to continuous life.) This rule can be generalized as  $E_1, E_2, \dots / F_1, F_2, \dots$  to define a family of *life-like* CA [Bays 2010]. The evolution of *discrete life* is deterministic and is completely defined by its initial state.

Standard MR and MR streaming both operate on KV-pairs. In MR streaming, each KV-pair has to be represented as a single line of text. Input, output, and intermediate datasets in 2D *discrete life* simulations represent living cells as KV-pairs in which the key part consists of the cells' coordinates (*row*, *col*) and the value part is empty. Cells that are not included in the dataset are assumed dead (Table 3).

Table 3: *Life* data representation – data sample

<i>Discrete life</i>	<i>Continuous life</i>
	1 1 0.0
	1 2 0.5
	1 3 0.0
2 1	2 1 1.0
2 2	2 2 1.0
2 3	2 3 1.0
	3 1 0.0
	3 2 0.5
	3 3 0.0

The initial *life* state is stored in one or more text files on the DFS before processing. An MR streaming job automatically splits the input dataset into independent blocks, which are submitted to mappers, one line per cell at a time (Figure 3). Mappers process individual cells and emit intermediate KV-pairs that are partitioned and sorted by the MR engine and then input into reducers. Reducers process intermediate KV-pairs and emit output results that are stored back on the DFS, one output file per reducer. The output dataset can then be used as the input for a subsequent MR streaming job. Hence, a single *life* simulation step is implemented as a single MR streaming job. A multi-step *life* simulation can be realized as a MR streaming job iteration by using tools that are outside of the MR streaming model. This pattern is followed for both *discrete life* simulations (discussed in this subsection) and *continuous life* simulations (discussed in the next subsection).

A single *discrete life* simulation step can be implemented by means of a technique known as MR *message passing* [Lin and Schatz, 2010]. For each input cell (by definition alive) a mapper can emit intermediate KV-pairs that are interpreted as messages to all of the cell's neighbors, alive and dead. Such messages from a living cell simply notify all of the cell's neighbors --- living or alive, and including the cell itself --- that the living cell belongs to those cells' neighborhoods. Messages to the same cell are dispatched to the same reducer, and each reducer receives all its messages in sorted order. This enables a reducer to count the living neighbors of individual cells, to determine the cells' next states (dead/alive) and to emit only living cells.

MR message passing can generate numerous small messages. Higher message volume can become a MR network bottleneck and be detrimental to performance. The number of messages can be reduced by applying local in-mapper aggregation (LA) optimizations [Lin and Dyer, 2010]. LA is applied to *discrete life* simulation in MR streaming as follows. For each neighbor of each input cell, the mapper increments (rather than emit immediately) a cell's counter within a local in-memory hash. Aggregated counts for each cell are emitted just before the mapper termination. Such aggregated counts for the same cell are summed up by a single reducer that determines the next state of the cell. A *discrete life* single-step

simulation algorithm in MR streaming referred to as *D-Life*, is shown in Figure 4. This algorithm assumes no size limits on the lattice and can operate on very large *discrete life* instances.

```

1: class Mapper:
2:   method Map ():
3:     hash =  $\emptyset$ 
4:     for line  $\in$  stdin:
5:       cell = (row, col) = Parse (line)
6:       Emit (cell, tag = Alive, count = None)
7:       for neighbor in Neighborhood (cell):
8:         hash[neighbor] += 1
9:       for cell in hash:
10:        Emit (cell, tag = None, count = hash[cell])
11: class Reducer:
12:   method Reduce ():
13:     last-cell = None;
14:     for line  $\in$  stdin:
15:       current-cell, tag, count = Parse (line);
16:       if current-cell  $\neq$  last-cell :
17:         if last-cell  $\neq$  None:
18:           if Next-State-Is-Alive (last-cell):
19:             Emit (last-cell)
20:           last-cell = current-cell; alive-neighbors = 0
21:           alive-neighbors += count;
22:       if Next-State-Is-Alive (last-cell): Emit (last-cell)

```

Figure 4: Single-step *discrete life* simulation algorithm in MR streaming (*D-Life*)

In the *D-Life* algorithm (Figure 4), the 2,3/2 rule and the Moore neighborhood of Conway's *discrete life* are encapsulated in methods Next-State-Is-Alive and Neighborhood. Hence, the *D-Life* algorithm can be applied to simulate other *life*-like CA by merely adapting the two methods to alternative rules and neighborhoods. *Larger than life* (LtL), for example, is a family of CA generalizing *discrete life* to large neighborhoods and general birth and survival thresholds [Evans, 2010]. Any LtL instance can be simulated by the *D-Life* algorithm with methods Next-State-Is-Alive and Neighborhood defined to properly implement the specific rule and neighborhood. Variations of *discrete life* in larger dimensions [Bays, 1987] can be simulated with the *D-Life* algorithm by merely extending the cell representation to a larger number of dimensions.

## Continuous Life in MapReduce

*Continuous life* is a CA with continuously valued states from the 0..1 range. *Continuous life* employs a transition rule that is formulated as a nonlinear expression with a temperature parameter  $T$  and two parameters:  $E0$  (energy shift parameter) and  $x0$  (state shift parameter). In the limit  $T \rightarrow 0$  and with appropriately chosen values for  $E0$  and  $x0$ , the behavior of *continuous life* coincides with that of *discrete life* [Adachi et al., 2004].

We rewrote the original *continuous life* transition function [Adachi et al., 2004] in an equivalent form that is more suitable for a MR implementation. Let us denote the state of a given cell at time  $t$  as  $S(\text{cell}, t)$ . In *continuous life*, each cell

undergoes transitions at discrete time steps according to the following set of equations.

- (1)  $S(\text{cell}, t + 1) = F(E(H(\text{cell}, t)))$
- (2)  $F(z) = b / (b + 1)$  where  $b = \exp(2 * z / T)$
- (3)  $E(x) = E0 - (x - x0)^2$
- (4)  $H(\text{cell}, t) = S(\text{cell}, t) + 2 * \sum_{\text{cell}' \in \text{Neighborhood}(\text{cell})} S(\text{cell}', t)$

For *continuous life* simulations in the MR streaming model, input, output, and intermediate datasets represent living cells as KV-pairs in which the key part consists of the cells' coordinates (*row*, *col*) and the value part is the cell's *state*. Hence, all cells are explicitly represented in *continuous life*'s datasets, in contrast to *discrete life*'s datasets which contain living cells alone (Table 3).

To implement a single *continuous life* simulation step in the MR streaming model, we combine the MR message passing technique with the *strip partitioning* optimization technique. MR message passing was introduced in the previous subsection for simulation of *discrete life*. Strip partitioning was proposed originally for large-scale relaxation algorithms [Radenski and Norris, 2013].

A mapper inputs KV-pairs of the form (*cell*, *state*) from the DFS. For each neighbor *cell'* of the input *cell*, the mapper aggregates in memory partial values of the term  $H(\text{cell}', t)$  according to equation (4). Locally aggregated partial values for each *cell'* are emitted just before the mapper termination as intermediate KV-pairs. Such aggregated values for the same *cell'* are summed up by a single reducer to determine the complete value of  $H(\text{cell}', t)$ . The reducer then uses this complete value to calculate the next state of the *cell'* according to equations (1) --- (3) and to emit the new state to the DFS.

In MR, the intermediate output of each mapper is directed to specific reducers by the MR *partitioner*. In general, given an intermediate key-value record, the default MR partitioner hashes the key into a reducer index for the record, balancing the load among reducers [Radenski and Norris, 2013]. In *continuous life* simulation, intermediate records are in the form (*key*= *cell'*,  $H_{\text{partial}}(\text{cell}', t)$ ). Because of hashing, adjacent cells are likely to be directed to different reducers, and thus output into different DFS files (because each reducer's output is placed by the MR engine into a separate DFS file). At the next simulation step, adjacent cells are likely to be submitted to different mappers (because such adjacent cells are likely to have been output to different DFS files at the previous simulation step and because different input files are submitted to different mappers). Thus, the default MR partitioner tends to disperse neighborhoods and reduce data locality, which impairs local in-mapper aggregation and is detrimental for performance. [Radenski and Norris, 2013] Fortunately, the strip partitioning optimization technique can help reduce dispersion and preserve data locality. With strip partitioning, a mapper sends whole strips of consecutive CA lattice rows to the same reducer. Technically, the mapper outputs intermediate KV-pairs of the form:

$$(\text{key}=(\text{strip}, \text{cell}'), \text{value}=H_{\text{partial}}(\text{cell}', t)),$$

where *strip* is an index that identifies individual strips of CA lattice rows. The *strip* index is calculated as  $\text{strip} = \text{row} /$

*strip-length* where *strip-length* is a simulation parameter. Because the *strip* index is part of the mappers' intermediate output, all cells from the same strip will be directed to the same reducer during partitioning (see Figure 3), possibly from different mappers. Therefore, such adjacent cells will remain in the same output file as produced by the reducer. This strategy preserves data locality during iterative simulation and promotes performance. The *strip* index is emitted by mappers to facilitate partitioning alone and is ignored by reducers upon its receipt as part of the key.

A *continuous life* single-step simulation algorithm in MR streaming based on local in-mapper aggregation and strip partitioning (referred to as *C-Life*) is shown in Figure 5.

```

1: class Mapper:
2:   method Map ():
3:     hash = ∅
4:     for line ∈ stdin:
5:       cell, state = Parse (line)
6:       hash[cell] += state
7:       for neighbor in Neighborhood (cell):
8:         hash[neighbor] += 2*state
9:     for cell in hash:
10:      strip-number = cell.row / strip-length
11:      Emit (cell, strip-number, hash[cell])
1: class Reducer:
2:   method Reduce ():
3:     H = 0; last-cell = None
4:     for line ∈ stdin:
5:       strip-number, current-cell, in-value = Parse (line);
6:       if current-cell ≠ last-cell :
7:         if last-cell ≠ None:
8:           Emit (last-cell, state=F(E(H)))
9:           H = 0; last-cell = current-cell
10:      H += in_value
11:      Emit (last-cell, state=F(E(H)))

```

Figure 5: Single-step *continuous life* simulation algorithm in MR streaming (*C-Life*)

For practical purposes, we assume that *continuous life* evolves over a finite rectangular lattice with periodic boundary conditions. This assumption prevents the otherwise unlimited growth of datasets in iterative *continuous life* simulation. While the *continuous life*'s lattice is assumed finite, it can be potentially very large in an MR implementation.

In the *C-Life* algorithm (Figure 5), the *continuous life*'s transition rule and the neighborhood are encapsulated in separate methods that can be adapted to alternative rules and neighborhoods, without any changes to the *C-Life* algorithm proper.

## General MapReduce Streaming Pattern

We have designed the *D-Life* and *C-Life* algorithms by following a general MR streaming pattern. Our pattern is outlined in Figure 6. The pattern describes a family of MR streaming algorithms that execute as follows (Figure 6):

- *Map* processes and aggregates locally each input KV-pair. Processing may consist of various actions, such as

emitting the KV-pair (as done in *D-Life*) and/or performing mathematical operations (as done in both *D-Life* and *C-Life*). Aggregation involves storing intermediate results locally in a hash.

- Just before termination, *Map* emits all aggregated results as intermediate KV-pairs, with the optional use of strip partitioning (as done in *C-Life*).
- *Reduce* processes and accumulate locally each intermediate KV-pair. Partitioning and sorting by key (Figure 3) guarantee that all intermediate KV-pairs with the same key are submitted to the same reducer in an uninterrupted sequence. Processing may consist of various actions, such as performing mathematical operations (e.g., increment in both *D-Life* and *C-Life*). Accumulation involves storing intermediate processing data locally (such as *alive-neighbors* in *D-Life* and *H* in *C-Life*).
- *Reduce* ends the processing of each uninterrupted same-key KV-pair sequence by calculating the key's final value and emitting an output KV-pair accordingly. (In *D-Life*, this involves deciding whether a cell will be dead or alive; in *C-Life* this involves calculating the cell's next state.)

```

1: class Mapper:
2:   method Map ():
3:     for input-kv-pair ∈ stdin:
4:       Process-and-Aggregate ()
5:       Emit-All-Aggregated ()
1: class Reducer:
2:   method Reduce ():
3:     for intermediate-kv-pair ∈ stdin:
4:       if Current-Key-Is-Different-From-Previous-Key ():
5:         Emit (previous-key, Final-Value ())
6:         Initialize-Current-KV-Pair-Processing ()
7:         Process-and-Accumulate ()
8:         Emit (last-key, Final-Value ())

```

Figure 6: General MR streaming pattern

## Cloud Implementation and Empirical Evaluation

We implemented our *D-Life* and *C-Life* MR streaming algorithms in Python and then used the implementations for empirical algorithm evaluation on Amazon's Elastic MR cloud. We chose Python because it is higher-level language that significantly shortens development efforts and time in comparison with other mainstream languages, such as Java or C++. Our experiments were performed with Hadoop 1.0.3 on an Elastic MR cluster of up to 17 large instances, a master instance and up to 16 core instances.

We experimented with two versions of the *C-Life* algorithm, designated as *C-Life-16* and *C-Life-0*. The *C-Life-16* version uses a strip size of 16. Our preference to a strip size of 16 is based on some preliminary performance experiments with various strip sizes. The *C-Life-0* version does not use the strip partitioning optimization at all, hence its strip size of 0.

We ran *D-Life*, *C-Life-16*, and *C-Life-0* on the Elastic MR cloud to measure their execution times. Execution times for the first simulation step can be influenced by the initial data layout; but once data are shuffled by the first simulation step, execution times stabilize. We measured execution times for

the algorithms' second simulation steps over randomly generated square lattices. The initial datasets for *D-Life* was generated with alive cell probability of  $p=0.5$ . Recall that only alive cells are represented in *D-Life*'s datasets; in contrast, all cells and their states are explicitly represented in *C-Life* datasets. Given the same lattice size, *D-Life*'s datasets are smaller than *C-Life*'s datasets proportionally to  $p$ .

Table 4: *Same-data* performance (in min) on up to 16 nodes

Nodes	1	2	4	8	16
<i>D-Life</i>	16.3	22.6	11.6	6.9	4.2
<i>C-Life-0</i>	32.2	39.7	29.4	17.2	11.0
<i>C-Life-16</i>	37.4	19.9	9.5	6.8	4.0

Figure 7: Visualization of *same-data* performance (in min, vertical axis) on up to 16 nodes (horizontal axis)

Table 5: *Same-load* performance (in min) on up to 16 nodes

Nodes	1	2	4	8	16
<i>D-Life</i>	2.0	3.1	3.2	4.0	4.2
<i>C-Life-0</i>	2.5	4.9	7.8	10.9	11.0
<i>C-Life-16</i>	2.9	3.6	3.3	3.8	4.0

Figure 8: Visualization of *same-load* performance (in min, vertical axis) on up to 16 nodes (horizontal axis)

With all algorithms, we performed *same-data* and *same-load* performance evaluations. For *same-data* evaluation, we

measured algorithms' execution times in minutes on MR clusters with  $i$  core instances,  $i = 1, 2, 4, 8, 16$  over randomly generated square lattices of approximately  $16 \times 10^7$  cells (Table 4 and Figure 7). For same-load evaluation, we measured the algorithms' execution times in minutes on MR clusters with  $i$  core instances,  $i = 1, 2, 4, 8, 16$  over randomly generated square lattices of approximately  $i \times 10^7$  cells (Table 5 and Figure 8).

Our performance measurements demonstrate that strip partitioning optimization --- used in *C-Life-16* but neither in *C-Life-0* nor in *D-Life* --- gives a performance advantage of *C-Life-16* over *C-Life-0* and *D-Life*.

- The execution time of *C-Life-16* for a single simulation step on 16 task nodes is 64% less than the execution time of *C-Life-0* for the same task (see data in last columns of Table 4 or 5).
- The execution time of *C-Life-16* decreases in a smooth and predictable manner with the increase of task nodes, in contrast to both *D-Life* and *C-Life-0* (Figure 7).
- *C-Life-16* scales much better than *C-Life-0* and a little better than *D-Life* (Figure 8).
- In terms of absolute execution time, the performance of *D-Life* seems to rival that of *C-Life-16*, especially for larger numbers of task nodes (Figures 7 and 8); yet simulation of *discrete life* is computationally less intensive than simulation of *continuous life* and *D-Life* operates on smaller datasets than *C-Life* (given the same lattice size).

## Related Work

Cellular automata have been extensively studied since the early days of a-life [Langton, 1986]. A recent book offers a representative collection of approaches to the simulation of complex systems by CA [Hoekstra et al., 2010]. Another recent book covers current developments specifically in the game of Conway's *life* research [Adamatzky, 2010].

Our work on distributed MR *life* simulation builds on the MR strip-partitioning optimization originally introduced for a MR relaxation algorithm [Radenski and Norris, 2013]. Message passing was first studied in the context of data-intensive graph algorithms [Lin and Schatz, 2010] and later adapted to MR relaxation [Radenski and Norris, 2013]. Local in-mapper aggregation was originally designed to speed-up data-intensive text processing [Lin and Dyer, 2010] and was adapted to DNA sequence analysis [Radenski and Ehwerhemuepha, 2013] and relaxation [Radenski and Norris, 2013].

Our proposed *D-Life* and *C-Life* algorithms perform only a single *life* simulation step. A multistep *life* simulation is an iterative relaxation process that cannot be directly expressed in the pure MR parallelism model. We are among those who iterate pure MR steps by means of custom scripts expressed in common general-purpose languages. Others modify the pure MR model and implement new MR frameworks to facilitate iterative MR processing, such as iMapReduce [Zhang et al., 2012] and Twister [Ekanayake et al., 2010]. Potential ease of use and performance benefits of such iterative frameworks for multistep large-scale *life* simulations are yet to be studied.

Distributed MR relies exclusively on the DFS for the representation of intermediate datasets, including messages

passed by our *D-Life* and *C-Life* algorithms. Using the file system for message passing can be detrimental to performance but can be avoided with problems that fit entirely in memory. *In-memory MR* frameworks, such as Phoenix [Talbot et al., 2011] and M3R [Shinnar, 2012] aim to accelerate relatively small MR parallel applications by using hash tables to store intermediate key-value records in memory rather than on the DFS. Substantial speed-up benefits of in-memory frameworks for *life* simulations seem likely but are yet to be investigated.

*Discrete life*, a simple CA capable of generating diverse complex behavior, has stimulated many to design basic and advanced algorithms for its simulations and implement them in software. Basic serial and parallel implementations of *discrete life* have proven so worthy as to be incorporated in the computing curriculum [Wick, 2005; Hochstein et al., 2005]. Advanced *discrete life* simulation algorithms have been studied in traditional parallel computing models: shared memory [Ma et al., 2012], distributed [Xia et al., 2004], and mixed-mode [Smith and Bull, 2001]. To the best of our knowledge, we are the first to apply and evaluate the emerging MR model's applicability to distributed *life* simulations.

Various software frameworks have been developed and used to emulate of lattice-based a-life models since the early days of a-life, a trend that eventually began with the first *discrete life* programs. Lattice-based a-life software emulators continue to be used and developed [Komosinski and Adamatzky, 2010, Part II]. Notable examples include Discrete Dynamics Lab (DDLab), a set of tools for simulation of CA and other discrete structures [Wuensche, 2011]; NetLogo, a multiagent programmable modeling environment [Tisue and Wilensky, 2004]; and EINSTEIN, a multiagent simulator of land combat [Ilachinski, 2004]. We are the first to study the usability of MR in the a-life context.

## Conclusions and Future Work

In this paper, we investigate the applicability of the MR streaming model to the simulation of discrete and continuous *life* CA. We chose *life* CA because of their simplicity, a feature that makes them attractive as an initial test bed for distributed MR simulation approaches. We use MR message passing, local in-mapper aggregation, and strip partitioning to design the *D-Life* and *C-Life* algorithms for the simulation of discrete and continuous *life* correspondingly in the MR streaming model. We also formulate a general MR streaming pattern that we have followed in our design of *D-Life* and *C-Life* and that can be followed for the design of other CA simulation algorithms in the MR streaming model. We implement *D-Life* and *C-Life* on Amazon's Elastic MR cloud and empirically evaluate their performance. Our experimental results show that strip partitioning can reduce the execution time of continuous *life* simulations by 64%. To the best of our knowledge, we are the first to propose and evaluate MR streaming algorithms for lattice-based simulations.

In future projects, our proposed MR streaming algorithms can be used as prototypes in the development of novel MR simulation algorithms for large-scale CA in general and for lattice-based a-life models in particular. The field of applications of our approach can possibly be extended to the

field of multi agent simulation (MAS). MAS can be done in the standard MR model on a small Hadoop cluster [Sethia and Karlapalem. 2011] but the feasibility of MR streaming for larger scale MAS on the cloud is yet to be investigated.

Future work should aim at performance improvements. Performance improvements can be achieved by using standard MR instead of MR streaming and by using in-memory MR instead of distributed MR.

- The MR streaming engine does not aggregate intermediate KV-pairs at all, while the standard MR engine does it automatically; aggregation by the engine can be more efficient than custom aggregation in a higher-level language such as Python. For similar reasons, I/O, including KV-pair parsing, can also be more efficient in standard MR in comparison with MR streaming. With the use of standard MR instead of MR streaming, the tradeoffs is simplicity and ease of use for speed.
- Distributed MR frameworks use a DFS for all input, intermediate, and output datasets. The total I/O time can be much larger than the actual processing time. I/O performance losses can be offset by using in-memory MR frameworks, instead of distributed ones, for datasets that can fit in memory. With the use of in-memory MR instead of distributed MR, the ability to process unlimitedly large datasets is traded for speed.

As future work, our *D-Life* and *C-Life* MR streaming algorithms and our general MR streaming pattern can be translated into the standard MR model and ported onto an in-memory MR framework, to evaluate the performance gains with standard MR and in-memory MR.

# Balancing the Costs and Benefits of Learning Ability

Kai Olav Ellefsen

## Abstract

We study the costs and benefits of plasticity by evolving agents in environments with different rates of environmental change. Evolution allows both hard-coded strategies and learned strategies, with learning rates varying throughout life. We observe a range of change rates where the balance of costs and benefits are just right for evolving learning. Inside this range, we see two separate strategies evolve: lifelong plasticity and sensitive periods of plasticity. Sensitive periods of plasticity are found to reduce the learning cost while retaining the benefits of learning. This affects the evolutionary process, by limiting genetic assimilation of learned characteristics, making agents able to remain adaptive after relatively long periods of environmental stability.

## Introduction

Learning has been selected for by the process of natural evolution because it increases the fitness of individuals. This ability has both *advantages* and *costs* associated with it. The costs range from the energetic cost of maintaining a machinery for learning, to the cost having to do some potentially fatal trial and error to enable learning. The result of these costs is that evolution will attempt to minimize the amount of learning and, when possible, replace plasticity with innate strategies. Together, the costs and benefits of learning lead evolution to find a solution that learns just as much as is necessary and at the times in the lives of individuals when learning is most beneficial.

In this paper we study two phenomena related to plasticity regulation, to gain a better understanding of how they affect each other. The first one is the *Baldwin effect*, which describes plasticity regulation across *generations*. The second is *sensitive periods*, which describes plasticity regulation across individual lifetimes. An introduction to these phenomena, and related research on them is given in the next section.

## Background

### Learning- Costs and Benefits

The benefits of learning are frequently documented in studies of interactions between evolution and learning (see for

instance Floreano and Urzelai (2001), Littman (1995), and Nolfi et al. (1994)). When studying interactions between evolution and learning, it is important to also remember that learning has a *cost*. It is the balance between the cost and benefit of learning that decides the final learning strategies followed by individuals resulting from an evolutionary process. A comprehensive overview of the costs and benefits of learning is outside the scope of this paper. See Mayley (1996a) for a good overview of these factors. An implication of the cost of plasticity, is that plasticity in organisms needs to have *adaptive value*. When possible, natural selection should reduce costs by replacing plastic responses with genetic mechanisms.

Costs and benefits will vary significantly between individuals and even in single individuals in different situations. For instance the benefit of learning will be larger in an infant than an adult who has already learned the most important rules for gathering food and avoiding predators. See Turney (1996) for a comprehensive discussion of the trade-offs between plasticity and stability, and how this changes in different circumstances.

**Modeling the cost of plasticity** Kerr and Feldman (2003) investigated how the reliability of stimuli affects the utility of long-term memory. The authors argued that the key to deciding the evolutionary advantage of learning, is the amount of variability in the environment. They suggested that the relationship between environmental variability and the utility of learning follows “Goldilocks principle”: For learning to be beneficial, environmental variability needs to “just right” – not too high or too low. Based on their results, the authors concluded that under rapidly changing environmental conditions, a short memory span is beneficial, and that a reliable world favors using more memory. Presumably, a completely reliable world would remove the need for memory at all, as responses could be hard-wired, but the authors did not consider multiple generations of individuals, so the possibility of genetically optimized responses was not present.

Dunlap and Stephens (2009) provided the first experimental demonstration, through experiments on populations of *Drosophila melanogaster*, that some types of environ-

mental change favor learning, while others select against it. Through an aversion learning experiment, the authors were able to identify two different types of environmental change that affected the evolved degree of learning in the fruit flies differently. The first type of change, termed *best-action fixity* describes to what degree the best action to take in the environment is always the same. A high value of this parameter indicates that a strategy always performing the same action will be successful. The second type of change, termed *reliability of experience* represents the fixity of the relationship between experience and the best action. This indicates to which degree it is *possible* to do associative aversion learning. The situation that most strongly selects for learning, is the one in which there is a high reliability of experience, and a low best-action fixity. The opposite situation selects for non-learning (fixed) strategies. This theoretical model was confirmed by experiments on a population of *Drosophila* over 30 generations.

In our experiments, focus will be on regulating best-action fixity – in other words, the action giving the most fitness is subject to change, but the feedback indicating to the agent whether an action was “good” or “bad” is always correct. This ensures that the agent can always learn the best action by association with the feedback signal. We believe Dunlap and Stephens left out part of the truth: as the fixity of best-action decreases sufficiently, learning will be *selected against*. This follows from Kerr and Feldman’s hypothesis that the utility of learning follows “Goldilocks principle”.

### The Baldwin Effect - Regulating Plasticity Across Generations

The Baldwin effect (Baldwin (1896)) is an interesting example of how evolution will regulate plasticity across generations to reduce costs. The effect suggests how learned traits may become encoded into the genome of individuals through an *indirect* mechanism.

The Baldwin effect has two phases. It is initiated by a change to the environment, which forces a population to adapt. In the first phase, learning accelerates the rate of evolution. The reason is that, because learning allows weak individuals to become better, it smooths the fitness landscape, making the “evolutionary search” simpler. This was demonstrated in (Hinton and Nowlan (1987)) for an extreme case where there was only one correct solution, and no fitness gradient to steer the evolution when learning was not present. Adding learning provided a fitness gradient, accelerating evolutionary progress. In this phase, the benefits of plasticity outweigh the costs, leading to an increasingly plastic population.

In the second phase of the Baldwin effect, *genetic assimilation* occurs, meaning that the learned traits gradually become part of an individual’s genotype. This is a result of the cost of plasticity. Mayley (1996b) points out that it is the varying cost/benefit trade-off of plasticity that enforces

Figure 1: The two phases of the Baldwin effect - First, the benefit of learning leads to an increase in average plasticity. Subsequently, the costs lead plasticity to drop off.

the changes in the levels of learning in an evolving population: Shortly after an environmental change, the benefits of learning are large, and learning is selected for. As the population is full of individuals that can adapt to the environmental change, the cost of learning puts the individuals with innately good strategies at an advantage, and this reduces the overall plasticity in the population. Figure 1 illustrates the Baldwin effect.

**Computational modeling of the Baldwin effect** A few experiments have been done on the Baldwin Effect using simple, evolving individuals. Most of these deal with a *fixed* environment, where an unadapted population is inserted. If the environment is allowed to change during evolution, analyses become more complex. However, as argued by Anderson (1995), it is not sufficient to study the interaction between learning and evolution in fixed environments. Certain interactions between evolution and learning, e.g. the ability of plasticity to act as a “buffer” against changes in the environment, are especially evident in variable environments.

Watson et al. (2002) studied the relationship between the complexity and stability of a learning task and the tendency for genetic assimilation to occur. Genetic assimilation was found to be most complete (eliminating the most learning) when the environment was highly unstable. For more stable environments, the degree of genetic assimilation was lower. These results may seem surprising, but they follow from the relatively short periods of stability the researchers investigated. The most frequent changes were so frequent that evolved responses performed better than learned ones. A slightly more stable environment gave a higher benefit of learning, so the learning rate never reached zero.

Mayley (1996a) studied the effect of two important variables on the amount of learning performed by individuals over many generations of evolution: 1) The cost of learning, and 2) the correlation between genotype and phenotype space. He found that both a *neighborhood correlation* between genotype and phenotype space and an evolutionary *cost of learning* was necessary to observe genetic assimila-

tion.

Sasaki and Tokoro (1999) studied how rates of change in an environment affected populations of individuals evolving with different rates of *heritability of acquired characteristics*. The authors saw signs of a Baldwin Effect in the environments with relatively small degrees of dynamic change. For environments with larger degrees of dynamism, however, no genetic assimilation was seen. This indicates that the Baldwin Effect needs a certain *degree of stability* to enter into its second phase. This proposition is supported by findings presented herein.

### Sensitive Periods - Regulating Plasticity Within Individuals

A sensitive period is a period in the life of an individual where environmental stimuli have particular importance in the development of a certain ability (Knudsen (2004)). Hubel and Wiesel's classic paper (Hubel and Wiesel (1970)) illustrates the concept: One eye of a kitten was sutured in various periods throughout life, and it was found that visual deprivation of one eye early in life would make that eye unable to follow the regular path of development. The result would be that the cat was blind on that eye, also when it was opened later in life.

**Computational modeling of sensitive periods** Bullinaria (2003) studied sensitive periods of learning, as part of a simulation of the human oculomotor system. By the use of an evolutionary algorithm, *age-dependent neural plasticity* was generated. The type of age-dependent plasticity arising from these experiments had parallels with biological sensitive periods. For the purposes of our discussion, the most interesting feature of sensitive periods is their ability to reduce the cost of learning, by shrinking the plastic period of individuals. Previous studies on evolution of sensitive periods (Bullinaria (2003), Kirby and Hurford (1997)) have also discussed the cost-reducing role of sensitive periods. In this paper, we want to study this more systematically, by evolving sensitive periods under different balances between the cost and benefit of learning. Also, we want to compare the genetic assimilation happening under sensitive periods with that happening under a constant plasticity, to see if a more focused learning period can in some circumstances reduce the pressure on going through genetic assimilation.

### Hypothesis

The hypothesis of this paper is illustrated in Figure 2, and it proposes a model for how the topics of the Baldwin effect, sensitive periods and the cost/benefit balance of plasticity are connected. The way we regulate the cost/benefit of plasticity is by regulating the *rate of environmental change*. Figure 2 shows how we hypothesize learning strategies are related to the rate of environmental change. In constantly changing environments, learning has no benefits, as there

are no lasting rules to be learned. We hypothesize that the cost of learning would eliminate all plasticity in such a situation. In a fully stable environment, we also hypothesize that learning will be selected against, for obvious reasons.

In between these two extrema, we believe we will find individuals with different degrees of plasticity. Adding some slow changes to the fully stable state will at first be handled by evolution: genetic changes can tackle the environmental fluctuations. But when the environmental change reaches a certain frequency, the limit of genetic assimilation will be reached, and learning will be beneficial, as evolution cannot track the changes by itself. When the changes are relatively slow, we propose that sensitive periods may be enough to handle them, allowing short periods of plasticity in individuals' life, without paying the cost of a lifelong adaptation. Finally, in situations that have a rapid (but not too rapid) rate of environmental change, lifelong re-adaptation will be necessary, and we propose that individuals will evolve to have a high learning rate throughout life, and not just in sensitive periods. In this context, we can view sensitive periods as a *compromise* between the inexpensive but slow adaptation of the genotype and the costly but rapid adaptation allowed by individual learning.

The idea that environmental variability and evolved plasticity are closely connected has been around for a long time (Bradshaw (1965)). However, only a few empirical studies have investigated this connection (see Komers (1997) for a review), and typically only for a couple of levels of environmental variability. A systematic exploration of many scales of environmental change is naturally difficult to implement in a biological experiment. Therefore, this paper attempts to take a middle ground between theoretic approaches and empirical studies, by using evolutionary computation to evolve individuals under a large range of environmental variation.

## Experimental Setup

### The Environment

The setup is a modification of the experiment in (Todd and Miller (1991)), designed for studying the evolution of associative learning. This experiment was concerned with a simple underwater creature that is born into a patch of an environment where it spends its entire life. Substances of two different colors continuously float by, and the only decision the creature needs to make, is whether to eat these substances or not. Substances can be either poisonous or nutritious, and the challenge is for the creature to decide which type of color to consume. The association between color and edibility is a function of the feeding patch the agent was born into, so it is not optimal for all creatures to use the same strategy. The authors studied how evolution and learning together can find good strategies for this associative learning task.

In this paper, the same setup is used to study the relationship between plasticity and degree of environmental change.

Figure 2: A hypothesized spectrum mapping the level of environmental stability to learning strategies in individuals.

Two important extensions to the experiment have been performed: 1) Learning is associated with a *cost*, simulating the biological costs of learning, and 2) The environment changes at regular intervals. The second extension means that instead of varying across *feeding patches*, associations vary across *time*. The environmental change is the same: a reversal of the color/edibility association. We regulate the change rate of the environment using a single variable, the *stability period* of the environment. This variable decides the number of generations between changes. Setting this below one means we have several changes per generation. For instance a stability period of 0.1 entails 10 changes per generation.

The timing of changes within a generation is randomly chosen. However, in *which generations* the change occurs is fully controlled by the given stability period. We do not add randomness to which generations see environmental changes, because we want the generational interval between changes to be fixed, in order to study genetic assimilation systematically.

### The Agents

As pointed out by Mayley (1996b), two conditions are necessary in any experiment on genetic assimilation:

1. The plasticity of agents needs to be under genetic control.
2. The characteristics expressed by plasticity must also be possible to express genetically.

In this experiment, these conditions were met by an artificial neural network (ANN) capable of both employing *hard-coded rules* and *neuromodulated learning* when deciding which substances to eat and which to avoid. An evolutionary algorithm decides the initial *connection weights* and the *learning rates* along the same connections in the network, meaning it can evolve both hard-coded and plastic individuals.

The neural network is shown in Figure 3. The dotted connections are plastic links, which have evolvable initial weights and learning rates. The other connections are hard-wired in the experiment. The connections attaching to other connections are *neuromodulators*. That means that they modify the learning rates in the links they affect. This way, reinforcement learning driven by the perception of rewards and punishments is achieved. When the associations in the

Figure 3: The neural network performing the substance association task. Rounded rectangles represent neurons. Arrows represent connections.

environment change, the agent will notice that actions lead to different reinforcing feedback than before, and alter its preferences based on the neuromodulated plasticity.

Arcs in the network are updated by the following learning rule:

$$\Delta w_{ij} = \eta * mod * |x_i x_j| \quad (1)$$

where  $\eta$  is the evolved learning rate, *mod* is the strength of incoming neuromodulation and  $x_i x_j$  is the product of pre-synaptic and post-synaptic activity, in other words a regular Hebbian update term.

As the equation shows, it is the *absolute value* of the hebbian update that is used in the calculation of the new weight value, since we want the *modulatory signal* to decide the direction of the weight change: negative modulation means whatever action was taken was a bad idea, so the weight of the link causing the action should be decreased. Positive modulation should have the opposite effect. In the absence of modulation (in other words, if  $mod = 0$ ), weights are not updated.

### Plasticity

An important question in these experiments is how the ability to employ age-dependent plasticity, potentially forming sensitive periods, affects the balance between genetic and neural adaptation. We ran the experiments with two different types of plasticity. In the first type (“static” plasticity), plasticity was constant throughout the lifetime of an individual, and regulated by a single evolved learning rate. In the second type (“dynamic” plasticity), a function was evolved, which controlled the plasticity level throughout agents’ lives with a 2 timestep interval - meaning plasticity levels could

Parameter	Value
Generations	200
Adults	15
Children	25
Crossover probability	0
Mutation probability	0.01
Genes per individual	3 (static) or 60 (dynamic)
Bits per gene	8
Elite fraction	0.1
Culling fraction	0.1

Table 1: Parameters of the Evolutionary Algorithm

change at most 50 times in the agents’ 100-step lifetimes. To produce a somewhat smooth age-plasticity mapping, the evolved function was smoothed with a window size of 8 around the current timestep. For each timestep, a value between  $-2$  and  $2$  was evolved, and this was averaged with the 7 following values to produce the plasticity value for that timestep.

### Evolutionary Algorithm

The system SEVANN was used for evolving learning rates in these experiments. SEVANN is a flexible system for designing experiments allowing evolution of neural network parameters and topologies. For details, see Downing (2010). The parameters of the evolutionary algorithm are given in Table 1.

Results were found to be most stable and evolvable when crossover was turned off. However, for adding realism to the model, investigating further how crossover affects these results is interesting for future studies. Evolved individuals employed either static or dynamic plasticity regulation, and this required a different number of evolved genes. In both cases, two of the genes coded for the innate strategy of individuals. The remaining encoded the plasticity for the rest of individuals’ lives.

## Results

### Change Rates and Learning Effort

To investigate the hypothesis illustrated in Figure 2, we evolved the learning efforts and innate weights of individuals under many different rates of environmental change. We did this both for learning rates allowed to vary throughout the lifetimes of individuals and for learning rates that remained constant throughout life.

Figure 4 shows the resulting evolved learning effort. The measured learning effort is proportional to the sum of learning efforts made in each timestep for an individual. When the learning effort is “dynamic” (in other words, allowed to vary with the age of an individual), we can identify four main learning strategies, corresponding to the four strategies we hypothesized in Figure 2. For changes occurring too

Figure 4: The learning effort made by individuals evolved under different rates of environmental change. Dots are measured values, the lines interpolate between measurements. “Dynamic” indicates a learning effort allowed to vary throughout the lifetime of individuals, while “Static” indicates a constant learning effort throughout life. Change rates are given as number of generations between each change. – Averages over 20 runs. Error bars show a 95% confidence interval of the means.

slowly or too rapidly, there is no benefit to learning. These observations are in line with the suggestion (Kerr and Feldman (2003)) that the utility of learning in a varying environment follows “Goldilocks principle”: Change rates need to be *just right* for learning to evolve.

When the change rate is within the range needed to evolve learning capacity (here, that range is from about 0.1 to 50 lifetimes between each change), we can identify two main strategies for the dynamic learners. The first main strategy is to stay plastic throughout life. This strategy is adapted for environments where change rates are so high that a sensitive period of learning would not allow an individual to keep track of environmental changes. We see this strategy evolve when there are from 1 to 10 changes per generation. Figure 5 shows the learning strategies of evolved individuals. The situation for a stability period of 1 represents a turning point, where individuals go from being plastic their whole life to having a sensitive period of learning early in life. For changes occurring less frequently than once per generation, individuals adopt the strategy of having a short period of plasticity early in life and staying non-plastic otherwise. This gives the benefit of being able to adjust to the current environment, while not incurring the cost of lifelong plasticity.

The results discussed so far are presented in a more compact form in Figure 6. This figure shows how the evolved learning efforts through life vary with the rate of environmental change. The same results were seen in Figure 4, but then without the “age”-dimension. Seeing how learn-

Figure 5: Average learning rate (brightness - darker means higher learning rate) through their 100-timestep lifetimes (y-axis) for the winner individuals of each generation of evolution (x-axis). – Averages over 20 runs.

Figure 6: The learning effort made by individuals evolved under different rates of environmental change. Dark rectangles indicate a high learning rate - so a column with a few dark and many bright rectangles indicates that this individual has evolved a sensitive period of learning. Change rates are given as number of generations between each change. – Averages over 20 runs.

ing efforts vary with age and change rates, confirms the four strategies we identified earlier. For too low and too high change rates, little effort is made to learn, as seen by the bright values at the left and right edge of the plot. The relatively uniform gray columns (stability periods from 0.1 to 0.5) indicates individuals learning throughout life. Finally, the columns with stability period from 1 to 20 shows individuals with evolved sensitive periods.

### Static or Dynamic Plasticity

Comparing “dynamic” (plasticity varying throughout life) and “static” (fixed plasticity throughout life) individuals helps clarify the role of sensitive periods in plasticity when balancing the costs and benefits of learning. It reveals some of the aspects we miss by making the simplifying assumption of a lifelong, constant learning rate, as has been common in studies of the evolutionary regulation of learning efforts.

As seen in Figure 4, the most striking difference between the two types of individuals is that dynamic learners can adjust their learning rate much more smoothly to the different rates of environmental change. Static learners, on the other hand, operate in an “on/off” mode. Too rapid or too slow changes lead to individuals evolved to avoid learning. Intermediate rates of change lead to individuals that invest very much in learning. The inability of static learners to tune their learning efforts through life also means that they will have to shut off their learning ability earlier as learning becomes less beneficial. Dynamic learners, on the other hand, will retain some learning ability also under conditions that are relatively poorly suited for learning. This can be seen at the extreme ends of the spectrum of change rates, where the learning efforts of dynamic learners fall quite slowly towards zero.

Another interesting way to compare static and dynamic individuals is to look at their respective *fitness values* before and after environmental changes. This comparison indicates how well individuals balance their learning efforts to reap the benefits but avoid the costs as much as possible. Figure 7a shows fitness values for the best individuals in the *generation before* environmental change. For instance, for individuals evolved with a stability period of 50, this means the last 49 generations of their evolution happened under stable environmental conditions. We see that dynamic plasticity regulation gives a significant fitness increase when change rates are in the region from every second to every tenth generation. This is also the region where sensitive periods are most important. For higher change rates, a lifelong plasticity is most beneficial, as we saw in Figure 5. For lower change rates, no learning is most beneficial, because individuals will have *genetically assimilated* their learned traits in this generation immediately before the next change, allowing them to reduce their cost of learning.

In the generation *after* environmental change, the situation is different, as seen in Figure 7b. Individuals with a dynamically regulated learning rate now have a benefit over

Figure 7: Graphs showing the difference in fitness values between the best evolved individuals with dynamically and statically regulated plasticities throughout life. Shown immediately before and after an environmental change. – Averages over 20 runs. Error bars show a 95% confidence interval of the means.

the static ones also when the environment has been stable for a long time. The reason is that static individuals rely more and more on genetic assimilation the longer the period of stability – meaning they are unable to respond well to the environmental change. Also notice the increase in variability between the plots, as seen in the error bars. This is a natural consequence of the environmental change: the best individual before the change will have converged to the same behavior in most runs – but their behavior in the new environment may not be the same.

The same effect can be seen by studying the fitness curves of individuals. In this case, we look at their fitness values *without* an imposed cost of plasticity. The fitness values we study here are proportional to the amount of foods the agent eats subtracted by the amount of poisons it eats – an indication of exactly how well it performs the association task. Figure 8 shows fitness values plotted over 200 generations of evolution. The sudden drops in fitness value are due to environmental changes, and the following climbs show re-adaptation of the individuals. Static individuals show much larger drops in fitness values as the environment changes, indicating that they have relied heavily on genetic assimilation of learned traits and eliminated much of their learning capacity. This is seen also in dynamic individuals, but to a much smaller degree – they are able to retain their learning ability for more generations, because it is not as costly.

For changes with a frequency above once per generation, the same pattern does not emerge. With such a high frequency of change, keeping a lifelong plasticity is beneficial, and static individuals often end up with a higher fitness as such a strategy is easier to evolve for them than for dynamic ones.

## Conclusion

By studying the evolution of learning strategies across a wide range of environmental change rates, we have observed four main strategies: For both too frequent and too infrequent changes, no learning evolves, as the cost of learning outweighs its benefits. For environmental change rates in the range suited for the evolution of learning, the two main strategies are 1) Lifelong plasticity, which is preferred when change rates are high, and 2) Sensitive periods of plasticity, which is preferred for relatively low change rates.

We have also seen that the ability to regulate plasticity through the lifetime of individuals has two important features that separate these individuals from those with a static learning rate: 1) Dynamic individuals show a less complete genetic assimilation when environmental changes are infrequent and 2) Dynamic individuals can gain the same benefit from learning while paying a lower cost when environmental changes have an intermediate frequency, by employing sensitive periods of learning.

These results illustrate that genetic assimilation and sensitive periods in learning have similar roles: reducing the cost of plasticity, while retaining its benefits. Because of their similar roles, they affect each other – for instance, sensitive periods reduce the need for genetic assimilation. Therefore, studying them together in the same model, is necessary to get a full understanding of the roles of these two phenomena.

## Abstract

Introducing the concept of replication strategies this paper studies the evolution of cooperation in populations of agents whose offspring follow a social strategy that is determined by a parent's replication strategy. Importantly, social and replication strategies may differ, thus allowing parents to construct their own social niche, defined by the behaviour of their offspring. We analyse the co-evolution of social and replication strategies in well-mixed and spatial populations. In well-mixed populations, cooperation-supporting equilibria can only exist if the transmission processes of social strategies and replication strategies are completely separate. In space, cooperation can evolve without complete separation of the timescales at which both strategy traits are propagated. Cooperation then evolves through the presence of offspring-exploiting defectors whose presence and spatial arrangement can shield clusters of pure cooperators.

## Introduction

Actions that are in the interest of the group but not necessarily to the immediate benefit of the individual are widely observed in the social and biological sciences. Understanding the emergence and sustainability of such altruism or cooperation still poses major challenges to evolutionary game theory and the recent decades have seen very active research in this field. For instance, a recent review article classified five different mechanisms that support altruism (Nowak, 2006). Here, we are mainly interested in one of them: network reciprocity, cf. (Szabó and Fath, 2007; Perc and Szolnoki, 2010) for recent reviews.

Network reciprocity summarizes effects that result from constrained interactions in structured populations in which agents interact with fixed and typically rather small sets of permanent neighbours. In this way interactions between parents and offspring are favoured, i.e. cooperation is supported through positive assortment of strategies. The literature about evolutionary games in structured populations goes back to the seminal paper of Nowak (Nowak and M., 1992) in which spatial games were introduced, observing and describing chaotic patterns of strategies in space. The work was extended in several ways to, e.g., include effects

of noise (Szabó and Toke, 1998) and asynchronicity (Huberman and Glance, 1993) in strategy propagation. Recent research has mainly focused on the evolution of cooperation in population structures modelled by complex networks, finding, e.g. that heterogeneous networks give a strong boost to cooperation (Santos et al., 2006). The latter findings have been extended to evolutionary models on regular graphs in which there is some heterogeneity in agent's abilities to generate payoff. Examples of studies in this direction are (Szolnoki and Szabó, 2007; Perc and Szolnoki, 2008; Brede, 2011a), but also the recent work on teaching and learning (Szolnoki and Perc, 2008; Tanimoto and Yamauchi, 2012). In the latter line of research agents are classified into two groups: (i) teacher agents with an enhanced ability to pass on strategies and (ii) learner agents with reduced abilities to pass on strategies. The co-evolutionary dynamics of fast and slow strategy spread can then generate phases in which cooperation can survive much beyond parameter regimes in which cooperation is supported by network reciprocity alone (Brede, 2013a).

Common to this large bulk of work on cooperation and network reciprocity is the assumption that offspring (in a biological context) or followers (in a social context) adopt exactly the same strategy as parents (or leaders). In fact, one might surmise that this assumption is crucial to allow for positive assortment which enables support for cooperation through network reciprocity. In this paper we introduce a more general framework that aims to challenge this hypothesis and explore its boundaries. We distinguish two traits that describe agent behaviour. The first is the typical social strategy that describes an agent's behaviour in the social dilemma game under consideration. The second is a replication strategy, i.e. a strategy that an agent will pass on as a social strategy to its offspring. In this way every agent is characterised by a tuple  $(s, e)$ : a social strategy  $s$  and a replication strategy  $e$  through which it can determine its offsprings' social behaviour. Notably, the social strategy and the replication strategy of an agent can be different: It might be in the interest of an agent to surround itself with offspring (or followers) that are of a different type than itself. Hence,

agents may surround themselves by un-like types, questioning the role of positive assortment by network reciprocity.

One might also interpret our framework as a very simple model of social niche construction (Powers et al., 2011). The term social niche construction was recently introduced to describe a situation in which agents can evolve preferences for the social group they interact with. Using the example of preferences for group size it was then demonstrated that co-evolution of such preferences and social strategies can naturally support cooperation. In our context here, by their replication strategy, agents can influence the environment in which they live and thus improve their chances to generate payoff in competitive games. Using the often-studied framework of the prisoner’s dilemma game, we will explore under which circumstances such a simple co-evolutionary model can allow for additional support for cooperative strategies.

Real-world inspiration for the above assumption of differences between social and replication strategies is not hard to come by. For instance, in models of teaching and learning the above framework allows for situations in which teachers can teach strategies different from their own. Arguably, this is a more realistic and general framework than the one considered in previous work. In a biological context one might interpret the model as a simple model of cell differentiation.

The present work thus follows in a line of recent advances in the understanding of the co-evolution of individual-level traits and cooperation (Szolnoki et al., 2009; Powers et al., 2011; Perc and Wang, 2010; Brede, 2011b, 2013b).

The organization of the paper will be as follows. We start with a detailed description of the model framework and then describe and explain results in the section thereafter. The paper concludes by a summary and discussion section that puts our main results into context and discusses implications and future work.

## Model

In more detail, we consider the following model of an evolutionary one-off prisoner’s dilemma in space. A set of  $N$  agents are associated with the sites of a graph whose links define interactions and directions of strategy propagation. In case of experiments in well-mixed populations this social networks is a complete graph, otherwise we perform experiments on an  $L \times L$  square lattice with von Neumann neighbourhoods. Agents are characterized by two strategy traits, a social strategy trait  $s \in \{0, 1\}$  and a replication strategy trait  $e \in \{0, 1\}$ . We use the convention that state “0” corresponds to a strategy of pure defect and state “1” corresponds to pure cooperate. Agents play a prisoner’s dilemma with payoff matrix parametrized in the conventional form

$$\begin{pmatrix} R & S \\ T & P \end{pmatrix} = \begin{pmatrix} 1 & -r \\ 1+r & 0 \end{pmatrix}, \quad (1)$$

such that the parameter  $r$  characterizes the toughness of the game setting. In Eq. (1)  $R$  stands for the reward for mutual

cooperation,  $S$  for the “sucker’s” payoff,  $T$  for the temptation to defect, and  $P$  for the punishment for mutual defection. A small  $r \ll 1$  corresponds to very mild dilemma settings, whereas  $r \rightarrow 1$  characterizes very tough dilemmas. Hence, we distinguish four strategies: (i) cooperators who want their offspring to cooperate ( $s = 1, e = 1$ ), (ii) cooperators who want their offspring to defect ( $s = 1, e = 0$ ), (iii) defectors who want their offspring to cooperate ( $s = 0, e = 1$ ) and (iv) defectors who pass on defection to their neighbours ( $s = 0, e = 0$ ). This model may easily be extended by including context-dependent inheritance, i.e. the offspring determining trait would then depend on the social strategy currently played, but we reserve a thorough investigation of this case for future work and concentrate on the simplest setup in this paper.

In the following we will also consider the impact of various timescales in the evolution of social and replication strategies. The spread of both strategies might occur on separate or similar timescales. In the case of joint strategy pass, an agent will adopt the desired social strategy of a parent as well as its replication strategy. In case of disparate pass, an agent might either adopt the parents’ desired social strategy or its replication strategy. To distinguish these cases and to investigate the effects of disjoint strategy pass we introduce a probabilistic framework for the spread of strategies: With probability  $p_s$  only the social strategy is imposed, otherwise, with probability  $p_a$  only the replication strategy is passed on, and in the remaining cases (i.e. with probability  $p_p = 1 - p_s - (1 - p_s)p_a$ ) the social strategy is imposed and the replication strategy passed on. The timescales of the spread of social and replication strategies are then given by  $T_s = 1/(p_s + p_p)$  and  $T_a = 1/(p_a + p_p)$ .

Hence, our evolutionary simulations consist of an asynchronous process iterating the following steps:

- Seed all agents with randomly chosen initial social and replication strategies.
- Randomly pick a focus agent, say  $i$ , and choose a reference agent  $j$  from one of its four von Neumann neighbours at random.
- Evaluate game interactions of the focus agent with its neighbours to determine its accumulated payoff  $\pi_i^{(\text{game})}$  and follow the same procedure to calculate the accumulated payoff  $\pi_j^{(\text{game})}$  of the reference agent from interactions with its neighbours.
- After evaluating game payoffs, a cost  $c$  is deducted from payoffs of agents who attempt to spread a strategy different from their social strategy, i.e.

$$\pi_i = \pi_i^{(\text{game})} - c(1 - \delta_{s_i e_i}), \quad (2)$$

where  $\delta_{ij} = 1$  if  $i = j$  and 0 otherwise. A cost  $c > 0$  accounts for the fact that imposing social strategies different

from your own might involve a costly effort to ‘convince’ the opponent. Unless otherwise stated experiments are carried out with  $c = 0$  and the influence of a non-zero cost is only evaluated at the end of the paper.

- In a next step, a focus  $i$  agent will adopt the strategy of the reference agent  $j$  with a likelihood that depends on the difference in payoffs, i.e.

$$P(j \rightarrow i) = \frac{\exp(\pi_j/\kappa)}{\exp(\pi_j/\kappa) + \exp(\pi_i/\kappa)}. \quad (3)$$

In the above equation the parameter  $\kappa$  introduces noise in the replication process, the larger  $\kappa$ , the larger the chance for inferior strategies to spread. In all following simulations we set the noise level to a relatively large value of  $\kappa = 1$ . This choice is motivated by reasons of computational feasibility, because the evolutionary dynamics becomes very slow for low levels of noise when the timescales of cluster expansion are dominated by the timescales of change of local configurations of  $s = 0, e = 1$  defectors surrounded by cooperators at the boundaries of clusters of pure cooperators/defectors which can become entrenched for a very long time (see also the results section).

- Strategy spread (with the probability  $P(j \rightarrow i)$  defined above) occurs in the following way. With probability  $p_p$  the reference agent will impose his desired social strategy and will also transfer his replication strategy ( $s_i = e_j$  and  $e_i = e_j$ ). Otherwise, with probability  $p_s$  only the social strategy is imposed ( $s_i = e_j$ ) and in the remainder of cases, i.e. with probability  $p_a = \frac{1-p_p-p_s}{1-p_s}$  only the replication strategy is passed on from  $j$  to  $i$  ( $e_i = e_j$ ). The timescales for joint or disjoint spread of the traits (parametrized via  $p_p$ ) and distinction of timescales for the spread of social and replication strategies (parametrized via  $p_s$ ) prove crucial parameters to understand the dynamics of social evolution in this context.
- The payoff evaluation and strategy updating steps are then repeated for a sufficiently large number of steps until a quasistationary state has been reached. Then, average concentrations of all strategy concentrations are sampled from another  $TN$  iterations (note that in this paper time is always measured in units of full lattice sweeps).

In the following we employ computer simulations of systems composed of in between  $10^4$  and  $1.6 \times 10^5$  agents to construct phase diagrams of parameter regions in which the evolutionary dynamics can allow cooperation to survive.

## Results

### Well mixed populations

Before discussing spatial simulations it is worthwhile analysing the case without network reciprocity, i.e. a well-mixed population in which individuals meet at random and

Figure 1: Dependence of the concentrations of defect and cooperate strategies on dilemma toughness for a well-mixed population of size  $N = 40000$  and noise level  $\kappa = 0.01$ . For  $p_p = 1$  cooperation can always survive, but for  $p_p < 1$  defection wins out for  $r > 0$  (and since they all overlap circles at  $n = 0$  are omitted for  $r > 0.01$ ).

strategies spread according to Eq. (3) on the basis of payoff gathered from interactions with the entire population. For simplicity, we will not distinguish timescales given by  $p_s$  and  $p_a$  and assume  $p_s/p_a = 1$  in the following. It is then straightforward to describe the evolutionary dynamics of strategy concentrations  $n_i$  by a set of rate equations in the form:

$$\dot{n}_i = \sum_{k,l} n_k n_l a_{kl}^{(i)}, \quad (4)$$

where the indices label the four possible strategies 00, 10, 01, and 11 and the matrices  $a^{(i)}$  contain information about conversions between strategies according to the rules set out in the previous section. It is worth noting that  $n_{00} + n_{10} + n_{01} + n_{11} = 1$ , i.e. there are only three relevant degrees of freedom.

For the transition matrices one finds:

$$a^{(00)} = \begin{pmatrix} 0 & 0 & -1/2 & -p \\ \beta P & \beta/2 & 0 & 0 \\ \beta/2 & 0 & \beta p & 0 \\ \alpha P & \alpha/2 & 0 & 0 \end{pmatrix}, \quad (5)$$

where we introduce the shortcuts  $\beta = 1 - p_p/2$ ,  $\alpha = 1 - p_p$ ,  $P = 1/(1 + \exp(-\Delta\pi/\kappa))$ , and  $p = 1/(1 + \exp(\Delta\pi/\kappa))$  to simplify notation with payoff difference between defectors and cooperators

$$\Delta\pi = n_C(1 + r) - (-(1 - n_C)r + (1 - n_C)) \quad (6)$$

$$= r, \quad (7)$$

where  $n_C = n_{11} + n_{10}$  is the concentrations of agents with social strategy cooperate.

For instance, if an agent with strategy 00 meets an agent with strategy 01, the agent following 00 will adapt its strategy with likelihood  $1/2$  (since both strategies achieved the same payoff). If strategy 00 learns from 01, there are three cases that need to be distinguished. (i) with probability  $1 - p_p$  00 learns the social strategy that 01 wishes to impose (i.e. 1) and 01's replication strategy (i.e. 1) and hence converts to strategy 11. (ii) with probability  $p_p/2$  00 only learns the social strategy 01 wishes to impose, i.e. 00 converts to 10 and (iii) 00 may only learn 01's replication strategy, i.e. 00 converts to 01. In all three cases 00 converts to a strategy different from 00, hence the entry  $a_{13}^{(00)} = -1/2$ . Similarly, if 10 encounters 00 the chance that 10 will learn from 00 is given by  $P$ . Either learning only the social strategy 00 wishes to impose (probability  $p_p/2$ ) or learning both the social strategy 00 wishes to impose and 00's replication strategy (probability  $1 - p_p$ ) will convert 10 to 00. Hence the entry  $a_{21}^{(00)} = \beta/2$ .

Analogous equations for the remaining three matrices  $a^{(10)}$ ,  $a^{(01)}$ , and  $a^{(11)}$  can be derived, i.e.

$$a^{(10)} = \begin{pmatrix} 0 & 0 & p_p/4 & pp_p/2 \\ -\beta P & -\beta/2 & -\beta P & -\beta/2 \\ 0 & 0 & 0 & 0 \\ Pp_p/2 & p_p/4 & 0 & 0 \end{pmatrix}, \quad (8)$$

$$a^{(01)} = \begin{pmatrix} 0 & 0 & p_p/4 & pp_p/2 \\ 0 & 0 & 0 & 0 \\ -\beta/2 & -\beta p & -\beta/2 & -\beta p \\ Pp_p/2 & p_p/4 & 0 & 0 \end{pmatrix}, \quad (9)$$

$$a^{(11)} = \begin{pmatrix} 0 & 0 & \alpha/2 & p\alpha \\ 0 & 0 & p\beta & \beta/2 \\ 0 & 0 & \beta/2 & \beta p \\ -P & -1/2 & 0 & 0 \end{pmatrix}. \quad (10)$$

The systems of equations (4) is a system of three non-linear equations. Even though an analytical analysis of stationary states might be possible, numerical integration of (4) provides enough insight for the present purposes. Figure 1 gives the dependence of stationary strategy concentrations obtained by numerical integration of (4) on the dilemma strength for two scenarios of strategy pass for  $\kappa = 0.01$  (note that noise levels should be measured per interaction, i.e. a very small value in the well-mixed case with all-to-all interactions corresponds to larger noise values on sparse grids).

The first, illustrated by square symbols in Fig. 1 corresponds to completely asynchronous strategy pass, i.e.  $p_p = 1$ . In this case for all  $r > 0$  the population is split into roughly two thirds defectors (equal halves of which carry both replication strategies) and one third cooperators (with again equal halves carrying both replication strategies). In

contrast, for any  $p_p \neq 1$  (round symbols) the social strategy cooperate is found to die out, i.e.  $n_{10} + n_{11} = 0$ , and the two social defect strategies share the population in equal proportions.

It is easy to understand why this is the case. Strategy  $s = 0$  and  $e = 1$  can earn the same payoff as pure defectors with  $s = 0$  and  $e = 0$ . However, in a well-mixed population it cannot profit from generating offspring who cooperate, because cooperation can be exploited by the entire population of defectors. Hence, agents with  $s = 0$ ,  $e = 1$  can generate the same number of 'offspring' as  $s = 0$ ,  $e = 0$ ; but their descendants die out without conferring an advantage on the parents. The situation is different if the spread of social strategy and replication strategy are completely separated: In this case the population of social cooperators is always reinforced by an inflow from the pool of social defectors with replication strategy defect (who earn equal payoff as pure defectors) and can also not be suppressed through interactions with pure defectors, because there is always a one-half chance that the cooperative trait survives due to separate strategy pass.

### Spatially distributed populations

As we have seen in the previous section on well-mixed populations, replication strategies that differ from social strategies can only support cooperation if the spread of social and replication strategies is completely separated. The reason for this is that social niche construction cannot operate in well-mixed populations: offspring that plays the social strategy cooperate can be exploited by the entire population and does not bestow any specific benefit to the parent who gave birth to it. Rather, the effect for strategies with replication strategy  $e = 1$  is negative: Their offspring will replicate less well than the parent because it can be exploited by the entire population of defectors. One would anticipate that this situation can be different in viscous populations. In the latter case, parents can accrue specific individual fitness benefits by surrounding themselves by cooperators. It appears reasonable to surmise that the consequential increase in reproductive fitness for parents might compensate for the loss in fitness of offspring, thus enabling cooperative strategy traits to survive. We will explore this scenario for spatial games in some detail below.

Figure 2 illustrates simulation results for the evolution of the four strategies in two typical settings in which replication of the two components of a strategy, social strategy  $s$  and replication strategy  $e$ , are to some extent disjoint ( $p_p = 0.6$ ). The figures also give the frequency  $f_c$  of mutually cooperative interactions. In the first setting with lower dilemma toughness (top panel), cooperation can grow to dominance. In the second with somewhat larger dilemma toughness (bottom panel), an equilibrium state in which all four strategies coexist is reached. Spatial arrangements of the strategies that correspond to such a mixed state are illustrated in Fig.

Figure 2: (Average) evolution of social and reproduction strategies for a prisoner's dilemma and average fraction of mutually cooperative interactions  $f_c$ . (a) With  $r = 0.18$  and  $p_p = 0.6$  when cooperation grows to dominance and (b) with  $r = 0.22$  when an equilibrium between the strategies is reached (on a  $200 \times 200$  torus with  $\kappa = 1$ ).

3.

These first experiments which we show in Fig. 2 illustrate two important points: (i) As hypothesised above, when including opportunities for social niche construction via replication strategies, cooperation can survive in spatial arrangements, even if strategy pass is not completely disjoint. (ii) Disjoint transmission of social and replication strategies can allow for the dominance of cooperation in regimes of dilemma games far beyond regimes normally supported by network reciprocity (i.e. for a typical spatial game with von Neumann neighbourhoods with  $\kappa = 0.1$  the extinction threshold for cooperation is around  $r_c = 0.021$  (Hauert and Szabo, 2004) and even somewhat smaller with  $r_c \approx 0.017$  for  $\kappa = 1$ ).

The typical spatial arrangements in Fig. 3 also provide an intuitive understanding why replication strategies can support cooperation in spatial settings. The figure shows the

Figure 3: Example configuration of an equilibrium arrangement of the four strategies (for  $r = 0.22, p_p = 0.6, \kappa = 1$ ). Colors are  $(s, e)$ : red (D,D), light red (D,C), green (C,C) and blue (C,D). (70\*70) C,D and D,C only occur at the boundaries of larger C,C and D,D clusters.

presence of large homogeneous clusters of pure defectors ( $s = 0, e = 0$ , dark red) and pure cooperators ( $s = 1, e = 1$ , green). Strategies with  $s \neq e$  only occur at the boundaries of these clusters. A cursory glance at Fig. 3 which is confirmed by the results shown in the bottom panel of Fig. 2 also suggests that the strategy  $s = 0, e = 1$  (blue) is far more prominent than strategy  $s = 1, e = 0$ . The reason is that a social defect strategy can earn larger payoffs than a social cooperate strategy.

Let us now consider the effect of  $s = 1, e = 0$  and  $s = 0, e = 1$  on the clusters of pure cooperators and defectors. When replicating in the direction of pure cooperators  $s = 1, e = 0$  either reproduces itself or (assuming disjoint strategy pass) it produces a defector with  $s = 0, e = 1$ . However, since  $s = 1, e = 0$  earns the same payoff as pure cooperation  $s = 1, e = 1$  can only invade clusters of cooperators via neutral drift. By the same token it only rarely gets a chance to replicate when competing against defection, and if so, it cannot reproduce itself (since any pure defector  $n$  would either only be influenced in its social strategy via the replication strategy, i.e.  $s_n = e = 0$  or would additionally imitate the replication strategy  $e_n = e = 0$  which correspond to its own strategy anyway). Hence,  $s = 1, e = 0$  impedes the spread of pure cooperation into clusters of pure defectors, but also, by transitioning into  $s = 0, e = 1$ , delays invasions of defection into clusters of pure cooperators.

What about the spread of the strategy  $s = 0, e = 1$ ? The propagation of  $s = 0, e = 1$  is more relevant at the boundary of clusters, since, following social defect, it will typi-

Figure 4: (a) Dependence of the frequency of mutually cooperative interactions  $f_c$  on the dilemma strength for various values of  $p_p$  on a  $200 \times 200$  torus. It becomes apparent that cooperation finds more and more support, the more frequent uncorrelated replication events become. (b) Dependence of the concentrations of the various strategies on the dilemma strength for  $p_p = 0.4$ . There are two phases dominated by pure cooperators or pure defectors (small and large  $r$  and an in-between phase in which all strategies can coexist). (c) In contrast, for  $p_p = 0$  only pure cooperators and pure defectors survive and the phase diagram from the standard PD without replication strategies is reproduced.

Figure 5: Dependence of critical thresholds for the extinction of strategies on the probability for disjoint trait propagation  $p_p$ .

cally harvest a larger payoff than  $s = 1, e = 0$ . On the one hand, when interacting with pure cooperation, it will always surround itself by pure cooperation. On the other hand, when interacting with a pure defector, it will either generate a  $s = 1, e = 0$  defector or cause a transition of the neighbour to pure cooperation. Hence, even though  $s = 0, e = 1$  exploits cooperators, it also shields clusters of cooperators from the invasion of defection and promotes the spread of the pure cooperate strategy.

When considering the role of all four strategies at the boundaries of compact clusters of pure cooperators and pure defectors it is also important to recognize that the strategy  $s = 0, e = 1$  will typically generate the largest payoff (because being on average surrounded by more cooperators than pure defect) and thus replicate most often. Even though

being thus most successful in terms of replication, it can only recreate itself indirectly – its offspring will never follow the same strategy.

The mechanism which supports cooperation in the simulations shown above principally works as follows. Offspring-exploiting defectors  $s = 0, e = 1$  are the most successful strategy, but cannot recreate directly, and, as a result, serve as support for cooperation. It is evident that in case of joint strategy propagation a 'checkerboard pattern' of  $s = 0, e = 1$  interspersed with  $s = 1, e = 1$  would be evolutionarily stable. However, since  $s = 0, e = 1$  cannot recreate itself and is only generated at boundaries of defectors and cooperators when disjoint strategy pass is allowed, without the presence of random strategy invasions or mutations such a pattern cannot evolve from random initial conditions (cf. Fig. 4 right panel). Moreover, this checkerboard pattern is not stable in the face of even small degrees of disjoint strategy spread (measured by  $p_p$ ). If  $p_p$  is sufficiently large, offspring-exploiting defectors support pure cooperation in two ways: (i) by shielding clusters of pure cooperators from the invasion of defection, and by (ii) serving as a source of pure cooperators, as a consequence of their own success in replication.

Figure 5 extends our earlier simulation experiments by giving the dependence of the frequency of cooperative interactions and strategy concentrations on the dilemma toughness. A clear dependence of the support for cooperation on the frequency of joint strategy pass  $p_p$  is evident and is further supported by the full phase diagram that illustrates the dependence of coexistence regimes and regimes in which single strategies dominate on  $p_p$ . As already indicated by the dependencies in Fig. 4 the coexistence regimes are typically rather small and regimes in which either pure cooperation or pure defection take over the entire population dominate the diagram of Fig. 5. Coexistence is only found in a small

Figure 6: Dependence of critical thresholds for the extinction of strategies on timescales for the spread of the social strategy ( $p_s$ ) and for the replication strategy ( $p_a$ ) for fixed  $p_p = 0.6$ . For  $r > r_0$  only pure defection survives, for  $r < r_1$  only pure cooperation survives and for  $r_0 > r > r_1$  all four strategies can coexist. The faster social strategies spread relative to replication strategies, the more support for cooperation. Also the coexistence region becomes larger the slower the spread of the social strategy.

borderline region between the regimes of pure strategy dominance.

It is also of interest to investigate the dependence of the support for cooperation on the relative timescales for strategy propagation. To explore this question, we set up experiments with a fixed frequency of disjoint strategy pass and vary the relative frequencies with which reference agents only impose their replication strategy as the desired social strategy of neighbours (i.e. with probability  $p_s$ ) and the frequency with which neighbours only learn the replication strategy of a reference (i.e. with probability  $p_a$ ). A typical phase diagram that summarizes our simulation experiments is given in Fig. 6.

Two observations stand out. First, the support for cooperation grows the more prominent the imposition of social strategies relative to the learning of replication strategies. This observation is consistent with our argument about the role of offspring-exploiting defectors. The more frequent the spread of social strategies, the more often they will generate pure cooperators. Second, the regime in which all four strategies can coexist becomes the larger the more frequently agents pick up the replication strategies of their references. This second finding is also intuitively clear from the same argument. The more often replication strategies are learnt, the more often  $s = 0, e = 1$  transitions into  $s = 1, e = 0$ , thus boosting the concentrations of other strategies.

A last point worth investigating is the role of a cost for strategy imposition. To investigate this point we presume

Figure 7: Dependence of critical thresholds for the extinction of strategies on costs for the propagation of unequal strategy traits  $s \neq e$  for  $p_p = 0.5$ .

that the behaviour in the standard game, i.e. imposing agents' own social strategy on neighbours, is free. In contrast, imposing a strategy different from an agent's social strategy needs "convincing", i.e. it comes at some cost  $c$ , cf. Eq. (2). The experiments carried out in this way allow us to test the stability of the standard framework and answer the question "Would differences between social and replication strategies evolve if teaching is costly?". To explore this question we fix the frequency  $p_p$  of disjoint trait transmission and assume that both traits spread at equal rates (i.e.  $p_s = p_a$ ). Figure 7 summarizes these experiments by presenting a phase diagram for the dependence of extinction thresholds on cost assumptions. Clearly, imposing a cost for producing offspring with social strategies different from an agent's social strategy reduces support for cooperation. Such behaviour would naturally be expected, since imposing costs penalizes the "mixed" strategies  $s = 0, e = 1$  and  $s = 1, e = 0$  and our previous argument relied on the presence of the first of those to support cooperation via the exploitation of offspring. Nevertheless, even imposing costs that are very substantial compared to game payoffs, cooperation can exist in regimes far beyond the support it would find from the network reciprocity of the spatial grid (with an extinction threshold of  $r_c \approx 0.017$ , see Fig. 4).

From the data presented in Fig. 7 it is also noteworthy that costs reduce support for the coexistence regime. Costs penalize strategies with  $s \neq e$  and hence mixed phases in which all four strategies can co-exist are increasingly suppressed the larger the costs imposed.

## Conclusions

In this paper we have introduced a simple way to explore social niche construction (Powers et al., 2011) on spatial networks. In our framework, on top of a social strategy every

agent is endowed with a second trait, a replication strategy, which allows the agent to determine the social strategy of its offspring. We then explored the co-evolution of social and replication strategies, subject to various assumptions about the timescales of spread of both strategy components.

Analyzing the dynamics of the co-evolution in the prisoner's dilemma, we have established that cooperation can only be supported in well-mixed populations if social and replication strategies are never both passed on from parent to offspring. In a social context this corresponds to the rather unrealistic assumption that the timescales of learning the respective traits are completely separated. In a biological context, this assumption translates into assumptions about the traits being located on uncoupled separate genes. As demonstrated by our exploration of the spatial prisoner's dilemma, the presence of a structured population can mitigate this strict condition. We have shown that in spatial settings cooperation can find very strong support, even if the simultaneous passing on of social and replication strategies is rather likely. The main driver of the support for cooperation is the prevalence of offspring-exploiting defectors which can generate the largest payoffs in the game. Offspring-exploiting defectors are found to be in a similar role as payoff-distinguished agents in (Perc and Szolnoki, 2008; Brede, 2011a): by virtue of their enhanced ability to pass on strategies they assume a "leadership" role (Zimmermann and Eguíluz, 2005). Different from previous models like (Zimmermann and Eguíluz, 2005; Perc and Szolnoki, 2008; Brede, 2011a), however, such agents with  $s \neq e$  never replicate identically and thus offspring-exploiting cooperators facilitate the spread of cooperation by surrounding themselves with cooperators.

We have also presented a number of further experiments that corroborate the robustness of the above finding. Support for cooperation is robust to changes of the timescales of strategy spread over several orders of magnitude and also the inclusion of substantial costs for imposing social strategies different from an agent's own social strategy do not alter outcomes in a qualitative way.

One may wonder if the framework in which we introduced replication strategies in this paper is too restrictive. In other words: Would our main findings be robust if replication strategies were context dependent, i.e. influenced by the social strategy of agents which replicate such that an agent in the role of a social cooperator may wish to impose a different strategy on its neighbours than when being in the role of a social defector? We reserve a more comprehensive analysis of this more general setting for future work.

# When congestion can be useful: modelling driver diversion behaviour in road traffic networks

## Abstract

The ability to accurately predict driver route choices is an important part of traffic assignment, the process of forecasting traffic flows on roads across a region. Many assignment methods only consider the presence of recurrent forms of congestion, such as during rush hour periods, and fail to incorporate non-recurrent congestion effects caused by irregular events such as road traffic accidents. This paper proposes an agent based driver route choice model which includes driver reactions to the presence of non-recurrent congestion, supposing that drivers learn relationships between congestion locations and adjust their expectation of network travel times en-route, potentially choosing to divert. By simulating an example network with mixed populations consisting of agents capable of diverting and not, the result is found that initially increasing the proportion of diverting agents from zero is beneficial to the system as might be expected, reducing the number of vehicles navigating the incident affected area, but beyond a tipping point agents can no longer perceive the presence of congestion prior to diverting and network performance decreases. The model not only demonstrates the conflict between agents adopting travel time reducing behaviour and its impact on system performance, but it also highlights the importance of modelling driver knowledge appropriately to reproduce plausible phenomena in simulation.

## Introduction

It is important to be able to predict the impacts on road traffic flows of potential interventions such as new road layouts or signal timings, construction of new homes and retail zones, or population growth over time. To assist with this prediction, which can suggest severity of congestion or levels of pollution, traffic assignment is the methodology which attempts to answer the question ‘what is the likelihood that drivers will use this route to travel from an origin point to a destination point?’. After establishing an expected level of vehicular demand between each origin and destination pair, the congestion causing feedback effect of many driver’s routing decisions is included in the assignment process.

In order to predict road traffic flows adequately a thorough understanding of how drivers make routing decisions is required. This can then be translated in to models of driver route choice behaviour which describe how relative

measures of route attractiveness inform final routing decisions, typically including key preference factors such as travel time, distance travelled or toll costs (Bekhor et al., 2006). Capturing the important motivations and other elements of driver choice, such as reactions toward the presence of congestion, is crucial in order to produce accurate models and subsequent traffic flow predictions.

Two types of congestion are generally considered to exist in road traffic networks. The first is congestion caused by vehicular demand exceeding capacity (in the form of maximum traffic flow) on a regular basis, such as during rush hour and other peak periods, known as ‘recurrent’ congestion, and is present (in some form) in most assignment methods. The second ‘non-recurrent’ form of congestion is caused by unexpected capacity reducing incidents such as accidents, road maintenance works or local surges in demand reducing excess capacity, and rarely features in practical traffic assignment applications. This work examines the extent to which the possible presence of non-recurrent congestion could influence traffic flows and accordingly the importance of considering it in traffic assignment.

Traditional assignment approaches adopt an aggregate approach to analysis, splitting overall demand according to the relative attractiveness or utility of whole route options with ‘usual’ road network properties and so ignoring any possibility of non-recurrent congestion. The recent rise of agent based models of route choice instead allow modelled drivers to make individual decisions based on their unique experience of the transportation network, allowing for learning strategies and the evolution of choice over time to be explored (Nagel and Marchal, 2006).

This paper examines a mechanism whereby agents, each representing single drivers, are able to react to new information regarding the presence of non-recurrent congestion en-route. If this ability provides agents with a different impression of road network characteristics causing them to act in a different but plausible manner to what would usually be predicted, then it can be considered an important aspect of driver choice which should be included in mainstream traffic assignment models.

The paper is structured as follows: firstly the current state of, and assumptions behind, traffic assignment methods and driver route choice models are provided. Then the underlying traffic interaction model used here is described followed by the novel behaviour model presented in this work. The behaviour model is implemented on an simple example road network and the outcomes and insight provided by this model are finally discussed.

### Modelling traffic flows at user equilibrium

Traffic flows between each origin and destination pair under consideration are generally assumed in predictions to be in a configuration known as ‘user equilibrium’, originally defined by Wardrop (1952). Here the generalised travel costs (disutility) to travellers of each used route is minimal and equal to any other, thus providing zero incentive for a driver to use a different route. Extensions to the definition of user equilibrium have been made since including ‘Dynamic User Equilibrium’, where travel times are equal and minimal in each departure time period (Peeta and Ziliaskopoulos, 2001), and ‘Stochastic User Equilibrium’, where a portion of travellers choose sub-optimal routes representing driver perception errors (Bekhor et al., 2006).

An aspect of route flow dynamics which has received relatively little attention from modelling research is the process by which transportation networks move to an equilibrium flow set from any initial flow configuration, such as when a network change occurs and route flows pass through disequilibrium states. Some models have been developed, such as a class of ‘day to day’ route choice models derived from the work of Horowitz (1984) which assume that daily traffic flow configuration is a function of flows on the previous day(s) which can tend towards an asymptotic equilibrium flow distribution as the number of simulated days tends to infinity. These models have been extended to consider the basins of attraction of multiple flow equilibria (Bie and Lo, 2010) and long term system behaviour (Smith et al., 2013). Crucially for this work, day to day route choice models have also been developed incorporating multi agent systems where each agent, representing a single driver, holds a unique, evolving impression of network attributes which guide future route choice decisions (Liu and Huang, 2007; Tiang et al., 2010). These methods have been found to give identical predicted traffic flow configurations to other assignment approaches (Snowdon, 2013).

### Driver reaction to non-recurrent congestion

Where non-recurrent congestion is considered in traffic assignment, it is generally represented as a capacity reduction occurring along a section of road which increases the travel time for a constant level of vehicular demand (Gao et al., 2008). To model drivers diverting to avoid congestion, Unnikrishnan and Waller (2009) introduce the concept of ‘re-course’ where drivers are modelled receiving up to date net-

work state information as they traverse the network, which is a technique also adopted by other traffic simulation tools (Sykes, 2010). In reality however many drivers will not be privy to such information and must rely on previous experience to guide network travel time expectations.

Modelling driver re-routing and its influence on route choice has previously been attempted in network representations which impose a spatial congestion structure externally to the model (Gao et al., 2008). In reality the location of queues move within-day as a result of driver routing decisions (Long et al., 2008), for example the consequence of drivers diverting to avoid non-recurrent congestion may introduce more non-recurrent congestion elsewhere in the network and clear the area initially afflicted. It is important for accurately modelling traffic flows that the outcome of drivers adopting diversion behaviour, and any impacts of potential diverting opportunities on initial route choices, is understood.

This work incorporates two main features in the traffic assignment process in order to capture both the effect of incomplete network information and of emergent spatial congestion structure as has been described. The first is the use of a cell transmission model, which models vehicle movements along road links and the build up of queues in parts of the network, and the second is a novel application of a coupled hidden markov model representation of driver knowledge given to agents traversing the simulated network.

### A cell transmission model of road traffic interactions and congestion propagation

In this work vehicle movements and interactions are captured using a Cell Transmission Model (CTM). The CTM used here is a reimplement of previous works (Long et al., 2008, 2011), extended from Daganzo’s original CTM (Daganzo, 1994). In this formulation a network  $G = (N, A, C)$  features a set of nodes  $N$  connected by a set of links  $A$  and includes a set of centroids  $C$  which are each attached to a single node  $n \in N$  and can represent origins and/ or destinations. In the CTM each link is discretized in to homogeneous cells and time is partitioned in to intervals such that the cell length is equal to the distance travelled by free-flow traffic in one time interval  $\delta$ . For example, here  $\delta = 5s$  and free flow vehicle speed ( $v$ ) is 15m/s so cell length is 75m. A time variable,  $t$ , advances by 5s at each simulation time step. Each cell also has a fixed capacity of vehicles which can reside inside it at each time step. The units traversing the cell transmission model are implemented as agents which each hold their own driver behaviour model.

At each time step, as well as advancing agents on to their next cells and links, a number of agents drawn from the population may be entered in to the simulation at centroids specified by the agents. Should an agent be unable to join the link connected to  $n$  they will join a centroid waiting queue and attempt to enter the network at each time step onwards. Each

simulated day agents are injected in to the simulation in the same order but the number of agents entering at each time step is randomly chosen (up to a limit of 5 per origin).

Unlike in previous implementations of the CTM, in this system each modelled agent holds a unique identity and attached behaviour model. Prior to arriving at a node, agents are interrogated for their turning intention and next link choice. The simulated day only comes to an end when all vehicles have left the network.

Equilibrium is hard to define in a stochastic traffic system since a degree of route choice ‘noise’ may ensure that flows never converge to a single stable set. When describing deterministic route choice systems, Bie and Lo (2010) define equilibrium as a route flow configuration which re-generates itself indefinitely. Here a heuristic method is adopted that the system is left to evolve for a period longer than is required to visually reach an equilibrium flow distribution.

### Modelling a driver agent’s network knowledge using a coupled hidden markov model

Previous work has reported positively on describing a period of observed road link conditions as belonging to a set of states including ‘free flow’, ‘mildly congested’ and ‘highly congested’ travel time distributions (Kwon and Murphy, 2000; He et al., 2006). In reality link states exhibit an often predictable spatial structure around the road network as queues propagate from a single starting point such as a busy junction or incident location and affect other regions. These correlations have been used as a basis for developing reliable travel time predicting algorithms (Min and Wynter, 2011).

Choosing the right number of states to represent road link performance and capture travel time variation sufficiently is not a trivial task. The appropriate set of states may vary by location and time of day under consideration. In their work, Kwon and Murphy (2000) use two states, free flow and congested, but this work uses three states to emphasise the distinction between minor and severe congestion. Drivers may experience any state regardless of its cause, but non-recurrent congestion may result in an unusual state set being experienced compared to under ‘usual’ recurrent congestion. States as used here only depend upon travel times alone:

**Free flow** Travel time on link is less than or equal to  $1.3 \cdot (\text{Free flow travel time on link})$

**Moderate congestion** Travel time on link is less than or equal to  $2.0 \cdot (\text{Free flow travel time on link})$  and greater than  $1.3 \cdot (\text{Free flow travel time on link})$

**Heavy congestion** Travel time on link is greater than  $2.0 \cdot (\text{Free flow travel time on link})$

The driver behaviour model proposed here focusses on allowing driver agents to learn link state structures through

the use of a Coupled Hidden Markov Model (CHMM). By learning link state structures drivers can re-evaluate the expectation of congestion elsewhere in the network based on that day’s experience. Traffic systems have previously been represented as CHMMs for predictive purposes (Kwon and Murphy, 2000; Herring et al., 2010) but have yet to be explored as the basis of an agent based driver knowledge representation.

### Model overview

A single hidden markov model (HMM) considers time as discrete and at each step can be in one of a number of unobservable (hidden) states,  $S$ . At each time step the model emits one of a number of externally observable symbols,  $V$ , with a given probability in each internal state,  $B = \{b_j(k)\}$   $j \in S, k \in V$ . A transition probability distribution describes the state which the model will be in at the next step given the current state,  $C = \{c_{ij}\}$   $i, j \in S$ . The probability of the model being in any initial state is given by a distribution,  $\pi = \{\pi_i\}, i \in S$ .

This work uses an extension to HMMs proposed by Zhong and Ghosh (2001) which allows for the consideration a network of *coupled* hidden markov models. The state of each HMM in the next time step is influenced not only by itself but also by the (hidden) states of other connected HMMs. Here the CHMM is achieved by extending both the system transition matrix to describe the influencing effect of model  $a'$  on model  $a$ ,  $C = \{c_{ij}^{(a',a)}\}$ , initial probability distributions,  $\pi = \{\pi_i^a\}$ , and also introducing a coupling matrix  $\Theta = \{\theta_{a',a}\}$  which defines how the set of HMMs are connected.

### Implementation details

Each driver agent is equipped with a single CHMM as described, with each HMM representing a single road link in the network. The goal of the model is to determine an expectation of travel time for a link  $a$ ,  $\varphi^a$ , both at the start of each simulated day and en-route once the state of other links elsewhere in the network has been observed. For this implementation the CHMM belonging to each driver agent is considered fully connected ( $\Theta = J_{|L|}$ ) although in their work Kwon and Murphy (2000) only connect HMMs considered connected in the road network. The relationships between nearby link states are not fully understood yet limiting the interconnectedness of the CHMM saves on computations and memory use required by the simulation.

Driver agents also store an associated expected travel time (in simulation steps, i.e. multiples of 5 seconds) for each state of each link,  $\Gamma = \{\gamma_j^a\}, j \in S, a \in A$ , which is adjusted by daily experience using the exponentially weighted moving average model where  $r^a$  is the experienced travel time on link  $a$  and  $\alpha$  is an externally set learning parameter (0.01 in this implementation):

$$\gamma^a = \alpha r^a + (1 - \alpha)\gamma^a \quad (1)$$

Once a driver agent has traversed a link  $a$  they observe the link's state exactly (i.e. each state is tied to only one observation,  $B = I_{|S|}$ ) so only the state in question's expected travel time is updated. The initial state distribution,  $\pi^a$ , is then updated directly as the average experienced proportion of occasions that the link was in state  $s$ . At the start of the simulation the probability of any link being in any state is equal and each state's expected travel time,  $\gamma_j^a$  = free flow travel time on link.

The expectation of travel time on network links at the start of any simulated day can then be simply found as  $\varphi = \Gamma\pi$ .

This model would be sufficient to ignore within day effects and determine an equilibrium set of route flows based on initial route choices alone. However this work sets out to incorporate the possibility of agents changing the expectation of a link's state en-route based on information relating to the state of other links obtained on the trip, within day.

The system transition matrix is updated at the end of each simulated trip,  $C = \{c_{ij}^{(a',a)}\}$ , as the experienced proportion of occasions that link relationships occurred. That is, for the HMM associated with link  $a$ , the state probability distribution describes the probability of link  $a'$  being in state  $j$  given that link  $a$  was in state  $i$ .

As an agent travels through the network, experience is accumulated in two sets which are re-initialised as empty at the start of each day;  $L = \{a\}$ , which stores the identifiers of experienced links, and  $O = \{o^a\}$  which stores the corresponding set of observed link states. This information is used to update the expected probability that link  $a$  will be in state  $i$ ,  $P(o_i^a)$  as the average expected state of link  $a$  given its relationships with each of the traversed links in the set  $L$ :

$$P(o_i^a) = \frac{\sum_{(a' \in L)} c_{a',a}^{o_i^a}}{|L|} \quad (2)$$

Thus the single expected travel time on link  $a$  can be re-evaluated en-route as:

$$\varphi^a = \sum_{i \in S} P(o_i^a) \cdot \varphi_i^a \quad (3)$$

To inform the choice model, the final utility of a route is given as  $\varphi \cdot -0.1$  (negative since travel time is a disutility). The discrete choice model used to determine the probability of an agent choosing a route is a path sized logit model (with calibrated parameter = 0.1) which takes in to account the overlap between route options as well as utility (Bekhor et al., 2006).

In this application of a CHMM the re-evaluation of HMM states occurs when the agent receives any new information about current link states, such as when leaving a link. The result of this is that the CHMM does not operate in fixed

time steps which would create unnecessary computations or information not being considered in network re-evaluations.

## A simulation of driver reaction to network incidents

As an illustration of the effects of incorporating the general CHMM agent knowledge representation, the proposed day to day traffic assignment method is performed on the network shown in figure 1 featuring a fixed vehicular demand of 7500 vehicles on each simulated day. The network consists of 13 links, 13 nodes and one origin to destination pair O0-D0. Each link is divided in to 10 cells with a capacity of 10 vehicles with two exceptions: link 6, which is divided in to 16 cells, and link 5, which is divided in to 3 cells.

Figure 1: The network structure under examination, also showing the cells associated with links and vehicles traversing the network in a non incident affected day.

The probability of all network cells being affected by incidents on each day is 0% except cell 9 on link 6, whose capacity drops from 10 to 3 when an incident occurs in the same manner as is shown in figure 2 which illustrates how congestion forms in the CTM. On any simulated day there is a 30% chance that link 9 cell 6 is perturbed in this way. All other constants are set as in the model definition.

There are two routes through the network here forward named as the 'major route' and 'diversion route' which consist of links  $[1, 2, 3, 4, 5, 6, 13]$  and  $[1, 2, 3, 4, 5, 7, 8, 9, 10, 11, 12, 13]$  respectively. The free flow travel times on the two routes are therefore 345 seconds

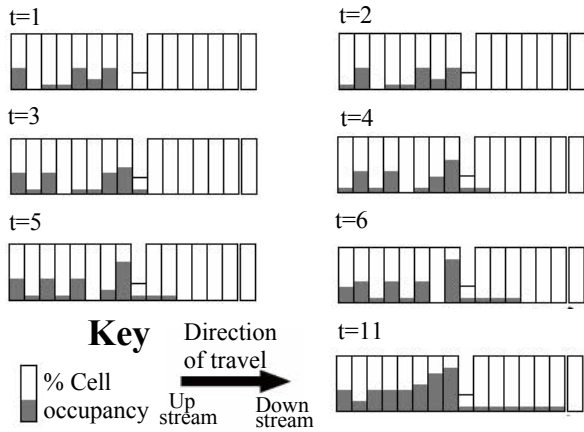

Figure 2: Cell transmission model output showing a stream of vehicles encountering a cell of lower capacity, resulting in the formation of an upstream queue.

on the major route (5.2km) and 565 seconds on the diversion route (8.5km).

Although the CHMM knowledge model presented here suggests that all agents should re-evaluate their decision en-route, in reality not all drivers will be able to do so either due to personal reluctance or lack of knowledge regarding the area and alternative route options. Accordingly, each agent holds the CHMM behaviour model as described except for the following key differences: *switchers* will re-evaluate their route choices en-route and may choose to divert (although it is important to remember that not all will, the discrete choice model only provides a likelihood of choosing a route rather than a decision) and *stayers* who will not re-evaluate any system perceptions en-route. As described in the literature overview, the vast majority of transportation forecasting models do not consider that agents will process information en-route, thus consist of a population of 100% stayers (0% switchers) who might be armed with perfect congestion information pre-trip.

Figure 3: Numbers of agents choosing the diversion route as their initial route choice against simulation day.

Figure 3 shows the day to day initial route choices of 7500 agents traversing the network in figure 1 over a period of 30 days. The population consisting of 100% switchers is capable of moving to an equilibrium which features fewer agents initially choosing the diversion route. This can be considered modelling the ability for switchers to ‘take a chance’ on the preferable major route and stayers being forced to consider average network performance in their routing decisions so more often initially choosing the diversion route.

As an analysis of within-day system behaviour, figure 4 shows the proportion of the agent population engaged in switching against time during a single incident affected day once route flows reached equilibrium (beyond day 50). The diverting proportion is calculated as the number of agents which have chosen to switch routes and are present on links 7, 8, 9, 10, 11 and 12 (the diversion section) against the number of agents present on links 6, 7, 8, 9, 10, 11 and 12 (the combination of the diverting section and incident affected link). As figure 4 shows, the 7500 agents take between 15000 seconds ( $\approx 4$  hours) and 30000 seconds ( $\approx 8$  hours) to pass through the network for the strategy mixtures examined.

Figure 4: Proportion of agents engaged in diverting throughout an incident affected simulated day at equilibrium.

As would be expected, for lower percentages of switchers present in the population the proportion of agents engaged in switching is capped by that percentage. It is logical that if few switchers exist in the population each will engage in diverting, enjoying a reduced travel time of close to free flow conditions on the diversion route. Due to the discrete choice model used, if an agent predicts that link 6 has a higher travel time than at the start of their journey, it only becomes *more likely* that it will divert, hence not every switcher agent chooses to divert.

The trend of ‘maximum numbers of switching agents divert’ would not be expected to continue with increasing the proportion of switchers in the population. If a population of 100% switchers exists and the maximum number divert then the major incident affected route would hold a close to free flow travel time and thus be faster than the diversion route.

Figure 5 summarises and extends figure 4, showing the

proportion of only the switching agents engaged in diverting during a 12500 second portion ( $\approx 3.5$  hours) of the simulated day for varying proportions of switchers. Below 60% switcher populations, the mean proportion of switchers engaged in diverting reaches 0.77, with the standard deviation decreasing to 0.09. Beyond 60% a clear system change appears in both figures 4 and 5 as the average proportion of agents diverting falls. There are two reasons for this; first the mechanism as described above suggests that some switching agents will choose not to divert - although this is few as figure 4 shows that the maximum proportion of agents diverting in a population of 100% switchers is close to 0.77. Secondly, the periodic ‘wave’ like diversion behaviour visible in figure 4 appears and at 100% switchers the proportion of agents switching is rarely steady as diversion behaviour regularly breaks down.

Figure 5: Mean and standard deviation of proportion of switching agents engaged in diverting between  $t = 2500$ s and  $t = 15000$ s.

To understand the impact of these trends on agent experience, figure 6 charts the average travel times between the route divergence point at the end of link 5 and route merge point at the beginning of link 13 (the same region examined by figure 4) experienced by switcher, stayer and *all* agents on an incident affected equilibrium day. This shows the (average) benefit to agents of adopting the two strategies. As has been discussed, prior to 60% switchers within the population, switcher agents enjoy a lower average travel time as stayer agents traverse the incident affected major route. Beyond 60%, the value of this benefit to switchers decreases even though in every simulation it is on average better for agents to adopt the switcher behaviour.

To examine the effect of varying population proportions on system performance, figure 7 charts the time required for all 7500 agents to pass through the network. As the proportion of switching agents in the population increases, up to around 70-80% switchers, the amount of time required falls, suggesting that the system can be considered to be acting in a *more* optimal fashion. Beyond 80% switchers in the population, despite the simulation consisting of more agents capable of making en-route diverting decisions in the hope of

Figure 6: Mean of travel times between diverging and merging points experienced by switcher, stayer and all agents during a single incident affected equilibrium day for varying proportions of switchers in the population.

decreasing overall travel time, the time taken for all agents to traverse the network *increases*.

The graph in figure 7 also shows the ‘optimal’ time required to complete an incident affected day from a simulation where the likelihood of link 6 being affected by incidents is certain. This simulation length is lower because uncertainty is removed from the system and network attributes do not change in the day to day model. Agents can each optimise their initial route choices through the evolutionary route adaptation process and at equilibrium do not need to alter route choices within day. Consequently the negative diversion breakdown does not occur.

Figure 7: Time required to complete the movement of 7500 agents at equilibrium on an incident affected day. Also shown is the ‘optimal’ time required when the probability of an incident on link 6 cell 9 is 1.0.

### Diversion breakdown and the role of information

The simulation result in figure 4 has shown how, for higher proportions of switching agents existing within the population, when an incident arises the number of agents engaging in diverting rises and falls in a wave like motion which has a negative impact on overall network performance.

To demonstrate how this trend arises, figure 4 shows a series of simulation outputs at six time steps on an incident

afflicted day (as shown by the capacity decrease on link 6). In a) ( $t = 1755s$ ) agents are joining the network and, due to the existence of congestion on the links leading up to the route diverging point, perceive link 6 to be in a highly congested state. At this early point in the simulation the upstream queue is still forming and few agents are diverting. In b) ( $t = 3990s$ ) the congestion stretches up the network but due to a larger number of agents engaging in diverting the size of the queue in each cell decreases - as in the peaks in figure 4. By c) ( $t = 5040s$ ) the reduced congestion on preceding links means that agents are no longer capable of considering link 6 to be in a highly congested state even though link 6 remains affected by the incident. At d) ( $t = 5530s$ ) few agents are engaged in diverting and most agents join link 6 believing it to be clear as in the troughs from figure 4. In e) ( $t = 5930s$ ) queues re-form on links preceding link 6 and by f) ( $t = 6490s$ ) agents once again perceive that link 6 is in the heavily congested state and again engage in diverting as in the peaks in figure 4.

The simulation has shown how, when an incident occurs, agents anticipate its presence and more agents which are capable of diverting do so, the queue on preceding links decreases and agents joining the simulation receive no information about any queues occurring ahead, so are unable to predict that link 6 is in a highly congested state. Thus all incoming agents naively remain on the major route believing it clear, eventually creating more queues which then back up the carriageway restarting the cycle.

Diversion breakdown has the result of decreasing network performance despite being caused by agents trying to decrease their own travel times, suggesting that in this simulation some level of queueing on upstream links can be seen as positive. In order to reduce average travel times in a network without information provided, some drivers are required to wait in congestion so that others can benefit from observing the presence of queues.

## Conclusions

This model has demonstrated a plausible road traffic phenomena in the form of diversion breakdown which is created in simulation by incorporating within the model both inter-vehicle interactions and a driver knowledge representation which focuses on experience gathered within trip and relationships between anticipated link states.

Although many other models of driver route choice exist, as well as models which explore other aspects of driver behaviour, this work has sought to explore the consequences of a single type of behaviour - adopting en-route diversions. Scope exists to incorporate the findings of this work with existing and future driver route choice models.

The findings from this model are also more relevant to real world road networks where users can be considered to be experienced. For example in areas where drivers are not expected to possess local knowledge, such as on major road,

Figure 8: Simulation outputs at a number of time steps exploring system behaviour on an incident affected day at equilibrium with a 100% switchers population. Agents occupying each cell are coloured according to their belief of the current state of link 6.

they may be reluctant to divert. Additionally, a driver unfamiliar with an area may hold their own potentially incorrect assumptions regarding traffic flows which will influence their routing and en-route diversion behaviour.

Network structure will also play a key role in whether and when diversion breakdown occurs and there may be multi-

ple opportunities for drivers to divert. Additionally, overall network performance is only improved if the diversion route can accommodate increased volumes of traffic which is uncertain, even unlikely, in most real world traffic networks.

To summarise, this paper has presented a plausible and general agent behaviour model of driver road network perceptions. Through the modelling of road conditions as belonging to one of a set number of states, a coupled hidden markov model can model the relationships between states and provide expectations of driver behaviour. The simulation has shown the competing pressures on drivers as choosing to remain on their initial route choices or be open to diverting on to alternatives.

## Abstract

The architecture of machine self-reproduction originally formulated by John von Neumann is studied within the artificial life system *Avida*. We describe a hand-designed von Neumann style self-reproducer, and report initial results from an exhaustive search of its single-point-mutation space. Unsurprisingly, the majority of mutants are simply sterile, and have no long-term evolutionary potential; however, automated characterisation and classification of the minority, fertile mutants proves to be difficult. We identify specific limitations of the standard *Avida* analysis tool for this particular purpose, and outline how it may usefully be enhanced.

## Introduction

The nature of machine self-reproduction was investigated by von Neumann, largely in the early 1950s (von Neumann, 1951, 1966). Inspired partly by Turing's abstract model of computing machines, von Neumann formulated a general architecture for self-reproduction, with a decomposition into active, constructive machinery and a separate, passive "description tape". This work significantly preceded the discovery of the structure of DNA in 1953, but reflects a similar abstract structure to that which is now known to support self-reproduction in biological organisms. Thus, in the von Neumann architecture, the active machinery may be considered as representing the *phenotype* and the passive description tape as the *genotype*.

This von Neumann architecture for self-reproduction is shown schematically in Figure 1. A parent machine (to the left) reproduces an offspring machine (to the right). A self-reproducer in this style consists of a phenotype  $P$  and a genotype  $G$  (or, in an individual, instantiated machine, these may be called "phenome" and "genome" respectively).  $P$  consists of a *programmable constructor* ( $A$ ), a *copier* ( $B$ ), a *control* ( $C$ ), and arbitrary "*ancillary*" machinery ( $D$ ).  $G$  is a tape that describes  $P$  (i.e. the assembly  $A+B+C+D$ ), relative to the specific description language, or "decoding" implemented by  $A$ . In operation,  $A$  decodes  $G$  (to produce another instance of  $P=A+B+C+D$ ),  $B$  constructs a copy of  $G$ , and  $C$  controls and co-ordinates these actions, ultimately detaching the complete offspring machine instance,  $P+G$ ,

identical to the parent and thus realising self-reproduction. As this basic architecture and self-reproducing functionality will be common for any arbitrary  $D$  (within the constructive capabilities of  $A$ , and assuming that  $D$  operations, whatever they may be, do not interfere with  $A+B+C$ ) this implies the existence of an indefinitely large space of self-reproducing machines, all connected via spontaneous perturbations of the  $G$  component (which therefore correspond to heritable mutations). Excluding such perturbation, and in the absence of resource constraints, any specific strain of such machine can exhibit exponential population growth. This potential for exponential growth, combined with mutation (variation) and resource constraints will give rise to conventional, neo-Darwinian, selection and evolution.

A significant additional feature that the von Neumann style of machine self-reproduction can theoretically exhibit is the evolvability of the genotype-phenotype mapping itself (McMullin, 2000) — i.e., of the "decoding" function implemented by the component sub-machine  $A$ . This possibility arises provided  $A$  is itself described (in a self-consistent way) within the genotype,  $G$ , and in sufficient detail that there exist potential mutations (perturbations of  $G$ ) that do change the decoding function implemented by the (expressed, mutated)  $A$  in the following generation. In general, this mutated  $A$  may or may not be capable of decoding the inherited genome (description tape)  $G$  in a way that still preserves the self-reproduction functionality; albeit, the *prima facie* likelihood is that such mutational events will fundamentally disrupt self-reproduction. For a change in the description tape to be truly inheritable, and for a consequent machine to be self-reproducing, the reproduction mechanism must somehow survive through mutational events, sustaining a genotype-phenotype mapping that is still applicable (i.e. "backward compatible") to the mutated description, so as to keep *self*-reproducing. The current paper is concerned precisely with exploring this possibility empirically, at least for one "toy" example of a von Neumann self-reproducer.

Figure 1: The schematic von Neumann style architecture of machine self-reproduction, excerpted from McMullin (2012).

### The Avida World

Although von Neumann originally elaborated his abstract architecture in the form of cellular automaton works, it can also be successfully implemented within *Core World* type systems. In a typical *Core World* type of system, user-designed machine-code programs (“organisms”) execute, reproduce, and compete for limited resources such as memory space and CPU time. As a result, those systems are expected to display evolutionary dynamics over time. Among others, the *Avida* system (Adami, 1997), which originated in the early 1990s, is an example of such a *Core World* formalism, but with an additional spatial structure. The latter is represented as a homogeneous two-dimensional grid of (virtual) microcontrollers (CPU + small local memory), each of which can instantiate a single running organism.<sup>1</sup> Typically initialised with one seed organism (*ancestor*), one can observe the population growth and evolution in each experimental run.

The standard *Avida* ancestor self-reproduces by means of self-inspection: the program copies its entire memory image word by word to create an offspring’s memory image.

<sup>1</sup>Although the *Avida* world superficially resembles to von Neumann’s early formulation of an abstract cellular automaton (CA) world, there are also fundamental differences. In the von Neumann CA, each node was a simple finite state automaton with no general purpose memory system; whereas each *Avida* node comprises a general purpose CPU and a substantial general purpose memory system.

This latter is (conceptually) divided off, and replaces the memory image in one of the neighbouring cells (see Ofria and Wilke (2004) for more detailed description). Once divided, the parent and the offspring organisms (each with a re-initialised/reset CPU state) continue execution according to their individual configuration (memory images). Such organisms will increase in number, and with mutation, variation may occur among the individuals of the population and give rise to evolution. Our investigation is conceptually similar to this standard *Avida* approach, except that the ancestor organism is designed with a von Neumann architecture instead of as a direct self-copier.

Computationally speaking, a genotype-phenotype mapping in this framework can simply be regarded as an arbitrary, Turing computable mapping between integers (representing the parent and offspring phenotype memory images). In the light of this, a mutable genotype-phenotype mapping through a mutable programmable constructor depends on whether two different such mappings, related via a perturbation on the description tape, can maintain backward compatibility with each other.

We have previously described the implementation and characterisation of a specific prototype von Neumann organism in *Avida*, implementing such a self-reproduction architecture, as a basis for investigating evolvable genotype-phenotype mapping (Hasegawa and McMullin, 2012). This design will now be briefly outlined.

## The Prototype von Neumann Organism

The phenome of the prototype program is coded using possible word contents defined in the Avidan instruction set (see Table 1). Along with the preset standard 26 Avidan instructions, the `read` and `write` instructions are also enabled for this investigation, in order to facilitate flexible reading of the description/genome  $G$ , and writing (construction) of the offspring phenome (memory image). The instruction set configuration in Avida defines what word contents are executable in a particular run, by sequentially associating “op-codes” (mnemonics) with natural numbers according to the order in which they are listed. This set defines possible word contents as numbers from 0 to 27.<sup>2</sup>

For the purposes of this example prototype, the genotype-phenotype mapping (decoding) is chosen to be a simple, sequential, block code. This is inspired by the biological genetic code, relating the sequential primary structures of DNA and corresponding proteins. However, unlike the biological genetic code, where the “alphabets” are different, disjoint, and of different cardinality (nucleotides and amino acids respectively), in our case the alphabets are identical (the distinct values of a single memory location, limited just to the sufficient set to represent each implemented instruction with one op-code, i.e., the numerical range 0..27, per Table 1). Further, choosing a fixed block size of one, this becomes essentially a sequential, monoalphabetic substitution function. This is conveniently implemented via a lookup table, of length 28. Each genome word is sequentially used as an index into this table to find the corresponding “decoded” word to be written into the (offspring) phenome. Note that, with such a coding scheme, a corresponding genome and phenome will always be of equal length; and that, unlike the biological genetic code, there is no redundancy (i.e., each possible phenome word value is represented by one, and only one, possible genome word value).

The designed prototype thus decomposes into the phenome, the first half, and the genome, the second half of the complete memory image. The phenome has five functionally separate regions, namely Decode Preparation, Decode Loop, Copy Preparation, Copy Loop, and Translation Table (see Figure 2 for the prototype’s schematic design and Table 2 for its region allocation and correspondence; find the actual program at our website referenced at the end of the conclusion section). In terms of the generic von Neumann architecture introduced earlier, the Decode Loop along with the Translation Table correspond to the programmable constructor  $A$ , the Copy Loop corresponds to the copier  $B$ , and Decode Preparation and Copy Preparation correspond to the control  $C$ .

The prototype incorporates von Neumann’s architecture

<sup>2</sup>The underlying memory word size is normally 32 bits wide. Numbers beyond the size of the instruction set are associated with the op-codes sequentially in a cyclic manner, so that every possible word value is also interpretable/executable as some instruction.

except for the (arbitrary) ancillary machinery  $D$ , which is not essential for reproduction per se (i.e.,  $D$  can be null, without violating the abstract architecture) and it is not relevant to our immediate investigation of mutations affecting the genotype-phenotype mapping (i.e. the programmable constructor  $A$ ).

The designed prototype organism has a total memory image of 644 words (i.e. 322 for each half, Phenome and Genome). Note that because the phenome corresponds to the genome on a sequential one-to-one basis, one can locate a unique genotypic word corresponding to any given phenotypic word. In practice, the Phenome segment was designed first, with the Genome segment of the same length being a “black box”. Then, the fully designed Phenome segment was reverse-translated into the corresponding Genome segment, so that the phenome and genome pair can produce the identical pair as an offspring.

Figure 2: The schematic design of the self-reproduction by the prototype.

Region	Address (in Phenome)	Code Address (in Genome)
<b>Decode Preparation</b>	0–27	322–349
<b>Decode Loop</b>	28–193	350–515
<b>Copy Preparation</b>	194–245	516–567
<b>Copy Loop</b>	246–293	568–615
<b>Translation Table</b>	294–321	616–643

Table 2: The five regions of the prototype’s phenome and the corresponding regions in the genome.

The Translation Table is a “data” segment in the Phenome: it is not to be directly executed (treated as containing instructions), but is referred to, as data, in implementing the decoding. Some concrete substitution code (permutation of the allowed word values 0..27) has to be arbitrarily chosen: we simply used the reversed sequence, 27..0 (i.e., 0 decodes as 27, 1 as 26, etc.).

Once the prototype is seeded in the Avida world, Decode Preparation and Decode Loop are initially executed and decode the genome to create the offspring’s phenome. One step of decoding is as follows: a source word is read from the genome (Decode1), and a destination word is looked up via the Translation Table (Decode2) and is written in a corresponding location in the prospective offspring’s phenome (Decode3). Subsequently, Copy Preparation and Copy Loop are executed and copy the genome to create the offspring’s genome. One word is read and written at one step (Copy1). For a complete self-reproduction, it takes 52218 Avidan instruction cycles (steps). This is the prototype’s *gestation time* (i.e. reciprocal of reproduction rate).

In previous work, we observed the prototype’s behaviour and characteristics as an ancestor. The design of the prototype proved to work out correctly, demonstrating one implementable instance of a von Neumann style self-reproducer within Avida, a Core World type of system. A noticeable finding from this work was that the self-reproducer can degenerate into a pure self-copier only through one step of single-point mutation in the course of evolution. That is, there is at least one possible mutational pathway for the ancestor to become a self-copier.<sup>3</sup> Though this could presumably happen through a longer gradual evolutionary process, the finding in this context suggests that even one step of

<sup>3</sup>Thus, it is theoretically possible to vice versa also: that the prototype can degenerate into a self-copier means that it is likewise possible for a self-copier (or, at least, that particular self-copier) to evolve to a von Neumann self-reproducer.

single-point mutation can bring about unpredictable changes in the behaviour of the prototype.

Still, it is not clear yet how typically the prototype potentially degenerates (or exhibits other similar phenomena); therefore it is legitimate to focus on the particular von Neumann style self-reproducer and to extend the investigation of its mutational pathways. This study can reasonably be a springboard to better understand the von Neumann style self-reproduction within the system, considering the vast space of possible strains of organisms in the current Avida setting. The space appears to roughly consist of reproducers and non-reproducers; further, the reproducers include self-reproducers and other kinds of reproducers; furthermore, self-reproducers may comprise self-copiers, von Neumann style self-reproducers and some other classes.

### Empirical Investigation: Point-mutation Space Search

For a better picture of the mutational pathways originating from the prototype, we first systematically counted out possible single-point mutants as candidates for organisms that have evolutionary potential, especially ones that maintain von Neumann style self-reproduction.

Candidates are obtained from the prototype's initial memory image by sequentially replacing a word content in each memory location of the genome with the other possible word contents listed in the instruction set and by expressing this change in a corresponding phenome. Each such candidate is an organism in Avida; or more properly, it is an initial memory image coupled with an initial virtual CPU configuration. Now, the genome size is 322 (the half of the whole length of the prototype), and the size of the current instruction set is 28. Considering the combination of the genotypic memory locations and the different possible word contents for each memory location (i.e., excluding the one originally existing in the location), the number of candidates is therefore 8694 ( $= 322 \times (28 - 1)$ ).

For the purpose of characterising the prototype, the candidates should ideally be classified by the "mode" of reproduction. However, reproduction mode classification is not straightforward, since a reproduction mode is not simply determined by a single attribute of reproduction or lineages, measurable when an organism is run and traced. Nonetheless, there are at least two distinct self-reproduction modes: the pure self-copying by inspection as in the standard Avida ancestor and the von Neumann style as in the prototype. Also, one can speculate that there may be various modes aside from, or in between, these two. At any rate, to effectively judge the reproduction mode, it is generally useful to analyse in combination the candidates' attributes (e.g. gestation time) and their execution profiles (e.g., instruction pointer traces and execution counts of particular instructions, such as the `write` and `h-copy` instructions, which write some content in a memory location). They, however,

do not yet necessarily guarantee what reproduction mode that a candidate uses. Rather, we need to observe how each offspring is created; besides, *viability* cannot be determined until the candidate's lineage is wholly traced for a proper number of generations.

As a preliminary step of the investigation, we attempted to classify the candidates by viability. Viability was judged initially by the Avida built-in analysis tool (specifically, using a `TRACE` command in a mode called *analyze mode*), which can trace a single lineage pathway starting from an incubated organism.

### The Analyze Mode

Technically, according to the `TRACE` command in the Avida *analyze mode*, an organism running for a given generation is classified into one of four possible classes:

- If no division occurs within a predefined cut-off time, the mode concludes that the starting organism is *non-dividing* (meaning non-reproducing); or else,
- If division occurs and the immediate offspring is identical, the starting organism is classified as *immediate self-reproducing*; or else,
- If division occurs and the offspring is not identical to the immediate parent, but identical to any of the (already traced) ancestors, then the starting organism is classified as *indirect self-reproducing*; or else,
- If division occurs and the offspring is identical to none of the direct ancestors, the starting organism is classified as *reproducing* (meaning non-self-reproducing); this final class potentially triggers a recursive analysis one further generation deep, unless terminated by reaching a maximum depth.

This automated analysis assumes a cutoff time, a certain window of maximum runtime, so as to judge as non-dividing or not. In order to be classified as some reproducing class, division must have taken place (i.e., the `h-divide` instruction must have been executed) before the cutoff time is reached; otherwise, the analysis run terminates classifying the organism as non-dividing. The cutoff time is set twice as long as the prototype's gestation time (i.e.  $104436 = 2 \times 52218$ ). This setting is reasonable considering the fact that the candidates can have varied gestation times. It is possible that, with a longer runtime, some candidates which are classified as non-dividing might be reclassified as reproducing. They are, however, unlikely to be selectively favoured over the original prototype ancestor in the Avida system, where fitness hinges on reproduction rate hence gestation time.<sup>4</sup> On the grounds of this, we can heuristically discard those classified as non-dividing.

<sup>4</sup>As opposed to these, the ones with shorter gestation time can potentially outnumber the others in the world where it boils down to the fitness, especially when the run is sufficiently long.

Out of the four classes, the non-dividing class indicates non-viability whereas the immediate self-reproducing class and the indirect self-reproducing class indicate viability. On the other hand, the reproducing class does not necessarily indicate viability or non-viability, as the offspring may or may not be self-reproducing; therefore only this class requires more generations to track down the lineage pathway in order to determine the viability. The analyze mode applies this classification repeatedly over generations as necessary to judge viability.

It is important to note that, in fact, the analyze mode only traces the offspring that is divided off from the parent at each division, assuming that viability means the ability to sustain self-reproduction on a single lineage pathway. To clarify this point, consider that each division can be regarded as making two offspring: one that used to be a parent, the other that has been divided off. The former replaces the parent and the latter replaces one cell in the neighbourhood, so spatially it appears that the parent remains sitting in the original cell and producing and placing one offspring into an adjacent cell. What is traced by this tool is the *divided-off* offspring, not the *sitting* one: only a single lineage pathway is revealed for each incubated organism (as opposed to the whole lineage with possibly multiple pathways).

### First-division Patterns

To support the somewhat limited analysis by the built-in tool, we applied a more refined classification based on certain patterns characteristic of the first-division event (for all cases other than simple *non-dividing*). This reclassification helps clarify the lineage pathways one-step further.<sup>5</sup> As pointed out earlier, division makes two organisms: the two offspring that the initially placed organism produces. One of the two offspring should be labelled as the organism that used to be the parent, and the other offspring as the organism divided off from the parent, which treatment is somewhat arbitrary. There are patterns in these three memories, depending on which of them are the same and/or different. Here, assume that an organism has an initial memory ( $I$ ; the parent's initial memory image) which becomes a final memory ( $F$ ; one of the offspring's initial memory image) when dividing off a child memory ( $C$ ; the other offspring's initial memory image). There are six division patterns at one attempt of division. Assume they are notated as follows using  $I$ ,  $F$ , and  $C$  for the sake of convenience:

- $I$ : Non-dividing;
- $I = F = C$ : Self-reproducing. Both of the offspring's initial memory images are identical to the parent's initial memory image;

<sup>5</sup>Although ideally all the attempts of division should be classified to investigate each organism's whole lineage, the automation of such classification requires considerable enhancement as discussed later.

- $I = F \neq C$ : One of the offspring's initial memory image is identical to the parent's, while the other offspring's is non-identical;
- $I = C \neq F$ : Essentially the same as the previous one, but this pattern is treated as self-reproducing by the analyze mode;
- $I \neq F = C$ : The two offspring's initial memory images are non-identical to the parent's, but identical to each other; and
- $I \neq F \neq C$ : Neither of the two offspring's initial memory images is identical to the parent's or to each other.

The first attempts of division in the candidates' single lineage pathways revealed by the analyze mode were studied and the candidates were reclassified based on these patterns.

## Results

The whole candidates distribute as shown in Table 3 when classified by "viability" using the built-in analysis tool and when by "fertility" based on the first-division patterns. As the analyze mode's ability to trace lineage pathways is not full, its "viability" judgment is different from what we originally meant: by viability we originally meant some continuous reproducibility with evolutionary potential. Here, in order to describe what is revealed by the analysis, we define *fertility* as follows: an organism is classified as fertile if its lineage is fully traced and in the lineage there is at least one strain that is classified as immediate or indirect self-reproducing.

Initially, of the whole candidates, the immediate self-reproducers (fertile, but only judged by tracing one offspring) accounted for nearly 10%, the pure non-reproducers (fertile, being non-dividing) for nearly 60%, and the rest 30% (fertile, but at least not immediate self-reproducing) remained unclassified.<sup>6</sup> The reclassification based on the first-division patterns revealed some of the unclassified that are infertile and discovered the others that have an untraced lineage pathway(s).

In other words, out of those initially classified as "viable", some lineages turn out not to have been fully traced; even though it is shown by the analysis tool that they have at least one viable reproduction pathway, they should be reclassified as unclassified. Those initially classified as "non-viable" are wholly reclassified as infertile without further scrutiny as they have no division executed. Out of those initially unclassified, some lineages turn out to have been fully traced, whether it be fertile or infertile, now putting fewer candidates in the unclassified.

<sup>6</sup>In hindsight, the analyze mode found no case of the indirect self-reproducing class among the candidates. As for the reproducing class, it found a few long cases with more than 300 recursions.

Immediate Classification	“Viable”	Unclassified	“Non-viable”	Total
Total	892 (10%)	2588 (30%)	5214 (60%)	8694

1st Division Pattern	Fertile	Unclassified	Infertile	Total
I	0 (0%)	0 (0%)	5214 (100%)	5214
$I = F = C$	871 (100%)	0 (0%)	0 (0%)	871
$I = F \neq C$	0 (0%)	158 (8%)	1745 (92%)	1903
$I = C \neq F$	0 (0%)	21 (100%)	0 (0%)	21
$I \neq F = C$	1 (3%)	11 (28%)	27 (69%)	39
$I \neq F \neq C$	0 (0%)	646 (100%)	0 (0%)	646
Total	872 (10%)	836 (10%)	6986 (80%)	8694

Table 3: Automated mutant “viability” classification (Top) and mutant fertility classification with the first-division patterns (Bottom).

Consequently, the fertile account for 10%, the infertile for 80%, and the unclassified (fertile but not immediate self-reproducing; may be infertile, reproducing, or indirect self-reproducing) for 10%. The combination of classifications allowed us to clarify which lineages of the candidates have been adequately traced and how much we have known about their viability.

## Discussion

The whole candidates were classified using the built-in analysis tool and based on the first-division patterns. Viability classification was not full lineage analysis due to some technical limitation. Nevertheless, viability was revealed to the extent that fertility classification revealed infertile, hence non-viable, candidates. The still unclassified candidates are all fertile but have untraced lineage pathway(s). With full lineage analysis, those candidates can be reclassified either as fertile (i.e., having some self-reproducing strain in lineage) or as infertile (i.e., having no self-reproducing strain

in lineage). From there, we intend to distinguish viability of the candidates, which indicates not only fertility but also evolutionary potential. These unclassified candidates are not negligible since we do not know a priori how frequently the candidates are fertile or viable. The classification should ideally be automated and systematised, even applicable to different sets of candidates.

## Search Limitation and Possible Enhancement

To emphasise the problem situation, the limitation of the current analysis tool surfaces when it hits either cases where (a) both of the two offspring that a parent produces are different from the parent or from each other, or where (b) one of the two offspring is the same as the parent but the other is different.<sup>7</sup> This fact implies that the built-in analysis tool assumes that even though an act of division produces two same offspring, tracing one of them suffices to analyse the lineage. Again, when the built-in analysis tool searches for descendant generations further down, what it recursively incubates for tracking is only one of the two offspring that is arbitrarily labelled as being divided off from the parent.

For example, suppose an organism produces one non-dividing offspring and one reproducing offspring in a deterministic environment without mutation. If the reproducing offspring produces a self-reproducing offspring, the original organism should be classified as (indirect) self-reproducing in that it exhibits the lineage. However, if the analysis tool is set to trace one of the offspring at the first-division, which happens to be non-dividing, then the other offspring, which happens to be reproducing a self-reproducing offspring, is not further traced, and the original organism ends up being classified as “non-viable”. This is not a proper viability classification because self-reproducers may be viable, with an evolutionary potential.

In other words, for some candidates which start out producing different two offspring, only a subset of (or rather, a “branch” of) the whole expected lineage becomes revealed through the analysis tool. Therefore, we can neither guarantee their fertility nor viability. Fertility implies reproducibility, whereas viability implies fertility with evolutionary potential, something that, for example, leads to an exponential growth of population (e.g. as pure self-reproducers), as opposed to a linear population growth<sup>8</sup>. Importantly, not only individually self-reproducing strains but also “collectively” self-reproducing strains (i.e., strains that are self-reproducing from a lineage point of view) should be classified as fertile, and even as viable, being evolutionarily po-

<sup>7</sup>The case (a) applies to the pattern  $I \neq F \neq C$  and the case (b) applies to the patterns  $I = F \neq C$ ,  $I = C \neq F$ , and  $I \neq F = C$ , in the notation introduced earlier.

<sup>8</sup>The *pathological constructor* proposed by Baugh and McMullin (2012) is an example, the strain of which reproduces itself and an infertile strain. This would exhibit the pattern  $I = F \neq C$ .

tential.<sup>9</sup> All this renders the classification non-trivial.

The automated analysis proceeds with the time limit as mentioned earlier and implicitly with the recursion limit (i.e., how many generations to track down deeper). Aside from these limits, because of the lineage traceability limit discussed above, not all of the candidates have been analysed for viability, although the majority of the candidates have been analysed for fertility.

It is our next, ongoing step to modify the analysis tool with an enhanced ability to fully cover the whole lineage pathways expected from an organism (although of course practically there should be set a division time limit and a recursion limit in automatically revealing lineages).

## Conclusions

In the previous research, we constructed and observed a von Neumann style ancestral self-reproducer with a genotype-phenotype mapping subject to evolution within the particular platform. The discovery of the self-reproducer's quick evolutionary degeneration into a self-copier raised a question: How likely is it such degeneration takes place? To answer this question, in the present research, we endeavoured to investigate the spectrum of single-point mutants of the particular self-reproducer in an attempt to classify *viable* candidates for evolvable genotype-phenotype mapping. The presented results are rather preliminary and should serve as a platform to further characterise the prototype self-reproducing in a von Neumann style. In the course, we consequently encountered a new situation where we ask: Given spectrum of mutants, can we classify them by viability?

The automated analysis, nevertheless, yielded an insight as to distinguishable *fertile* candidates, when combined with the classification of the first-division patterns. The fertile candidates (10%) need further scrutiny for reproduction mode and evolutionary potential, while the infertile candidates (80%) need not since they are logically non-viable. At any rate, while the vast majority (90%) of the whole candidates are classified as either fertile or infertile, the rest (10%) of the whole candidates yet remain unclassified.

The existence of those still unclassified candidates clarified the fact that there is a subtlety in the concept of viability. Specifically, the current analysis tool is only capable of revealing a single possible lineage pathway that an organism is expected to exhibit. To recapitulate, it traces only one (arbitrarily pre-determined) of the two offspring at each division, whereas the sub-lineage extending from the other offspring is not further traced. In this sense the analysis is not thorough. It is therefore necessary to automatise and systematise the classification of candidates based on viability, and further, based on the mode of self-reproduction, in the current system. The built-in analysis tool is being enhanced to

thoroughly investigate lineage pathways. A better characterisation of the particular example of a von Neumann style self-reproducer requires to understand its mutational pathways from a viewpoint of viability.<sup>10</sup>

<sup>9</sup>This distinction appears to be in resonance with that between individual autocatalysis and collective catalysis in artificial chemistry.

<sup>10</sup>Furthermore, to effectively find interesting reproduction modes in viable candidates, it may be practical to reclassify the candidates based on the likelihood of experiencing a change in genotype-phenotype mapping. In the design of the prototype, the regions where mutation most likely can cause any change in genotype-phenotype mapping are Translation Table and Decode Loop, both serving as a part of the programmable constructor *A* of von Neumann's architecture.

# Emergence of diverse behaviors from interactions between nonlinear oscillator complex networks and a musculoskeletal system

## Abstract

To understand the relationship between brain structure and behavior in the general movements of fetuses and infants from a complex systems perspective, we investigated how behaviors emerge from interactions between complex networks of nonlinear oscillators and musculoskeletal bodies. We prepared a snake-like robot and some network structures in a physical simulator. The various conditions imposed on the networks were (a) no connection among oscillators, (b) scale-free network, (c) one-dimensional lattice, (d) small-world network, and (e) random network. In the experiments, the robot exhibited multiple crawling and bending behaviors. By estimating the numbers of behavioral attractors, we revealed a qualitative difference between the scale-free network and other complex networks.

## Introduction

Animals and humans exhibit various adaptive behaviors. These behaviors likely emerge from complex interactions among environment, body dynamics, and brain activities, rather than from any single factor, posing several questions. How do the behaviors emerge? What underlying structure shapes such a complex and adaptive interaction? Do diverse interactive behaviors among systems emerge under any specific condition? To answer these questions, we must understand the relationship between structure and functionality in biological entities from a complex systems perspective.

Kuniyoshi and Suzuki (2004) proposed a model in which adaptive behaviors emerge through body constraint as a chaotic coupled field. In this model, on the basis of coupled map lattices and globally coupled maps (Kaneko and Tsuda (2003)), transitional adaptive behaviors should emerge as chaotic itinerancy among behavioral attractors. The model connects each chaotic element (logistic map) to a single linear actuator (muscle); that is, the actuator receives the chaotic elements output as a motor command and sends the outputs of its length sensors back to the chaotic element. The body structure behaves as a coupled field of deterministic chaotic activities. However, when the model is executed, the number of emerged behaviors is less than expected, indicating that chaotic itinerancy was suppressed.

Figure 1: Emergence of behaviors modeled as interactions among nonlinear oscillators and bodies. (a) The model of behavioral emergence based on chaotic coupled field (Kuniyoshi and Suzuki model). (b) Model proposed in this paper. The emergence model interacts with nonlinear oscillators possessing a certain complex network structure.

Complex network structures in the human brain are regarded as either small-world networks (Watts and Strogatz (1998)) or Scale-free networks (Barabasi and Albert (1999)). We are interested in the functional role of such brain structures.

This paper proposes a first step for investigating the emergence of organisms versatile behaviors by a constructive approach. To this end, we constructed a simulator built from complex nonlinear oscillator networks and a snake-like musculoskeletal body model. We analyzed and compared the emergent behaviors from the coupled dynamics of the musculoskeletal body and complex network structures.

## Behaviors and brain structures

### General movements of fetuses and infants

General movements, defined as purposeless whole-body movements, characterize the movements of fetuses and infants. The movements begin at about eight weeks gestation, and continue to evolve in healthy infants after birth. Within the first two months of birth, infants develop writhing movements, characterized by small-to-moderate amplitude and slow-to-moderate speed Prechtl (2001), although the arms may move rapidly and largely at this stage. After two months, fidgety movements appear, which are characterized by simultaneous variable acceleration of all moving parts of the body with other gross movements. After about 20 weeks, infants gradually develop voluntary movements.

Such movements are considered to be generated by the medulla oblongata in the brain stem. Anencephalic infants, who lack the neocortex, can move their whole body roughly and rapidly. Additionally, since the quality of general movements is related to white matter, the neocortex might be responsible for movement control Spittle et al. (2008).

### Brain structure and complex network theory

What kind of structure exists in the brain? This question has been answered by diffusion tensor imaging (DTI), which visualizes the nervous fiber connectivity in white matter. The brain structure is a variant of small-world networks, known as a rich-club network (van den Hauvel and Sporns (2011)).

A small-world network is one in which any two nodes are connected through very few interceding nodes, compared to the network size. Mathematically, in a small-world network, the average minimum distance  $d_{ji}$  between two nodes  $i$  and  $j$  is proportional to the logarithm of the total number of nodes  $N$  in the network. Thus, the small-world network satisfies (Watts and Strogatz (1998))

$$d \propto \log(n). \quad (1)$$

Scale-free networks are frequently encountered in complex network theory. In this type of network, connections are concentrated among several nodes, and the majority of nodes have only a few connections. Scale-free networks are characterized by the power law

$$P(k) \propto k^{-\gamma}, \quad (2)$$

where  $k$  is the number of edges from a node,  $P(k)$  is the probability of  $k$ , and  $\gamma$  is a constant. These networks are considered to be controlled by a small number of hub nodes.

### Brain rhythms and nonlinear oscillators

Brain activities manifest as brain waves of certain frequencies, which are synchronized or desynchronized depending on internal and external situations (Buzsaki and Watson (2012)). This synchronicity is called functional connectivity, while the anatomy of the nervous fiber tracts observed by

Figure 2: Distribution of degree of connection to one node in each network

DTI is called structural connectivity (Sporns (2012)). One of our interests is to elucidate how anatomical structures induce functional structures.

Oscillatory activities are observed not only in the neocortex but also in the brain stem. As mentioned above, such oscillatory activities are often modeled by nonlinear oscillator equations. As is well known, coupled nonlinear oscillators show deterministic chaotic activities such as synchronization, desynchronization, and great chaos, which is an exploratory behavior (Tsuda et al. (2004); Asai et al. (2000)).

### Chaotic itinerancy by chaotic activities coupled through a body structure

Kaneko and Tsuda (2003) proposed two coupled chaos models – coupled map lattice (CML) and globally coupled map (GCM) – which are suitable for general investigation of complex systems. They found that the models generate both ordered and disordered patterns such as deterministic chaotic itinerancy. Inspired by these models, Kuniyoshi and Suzuki (2004) proposed that adaptive and exploratory behaviors such as chaotic itinerancy could be induced by coupling chaotic elements through a robotic body as a physical constraint. As mentioned above, this model shows adaptive behaviors in varying environments, but exploratory behaviors are fewer than expected.

### A model based on interactions between the body and complex networks.

#### Complex network

Several real-world networks are considered to be scale-free or small-world. Such a network structure applied to chaotic elements generates synchronized clusters among chaotic elements (Jalan et al. (2005)).

Figure 3: Conceptual diagram of the model

**Small-world network and random network** Watts and Strogatz (1998) proposed that small-world networks can be generated by reconnecting a coupled map lattice as follows:

1. Start from a ring lattice of  $n$  nodes coupled to neighboring nodes up to a specified distance  $m$ .
2. Rewire each edge randomly with probability  $p$ .

z The behaviors of these networks are varied by reconnecting each connection in CML with probability  $p$ . The network is purely CML and completely random at  $p = 0$  and  $p = 1$ , respectively. Typically, small-world properties emerge between  $p = 0.01$  and  $p = 1$ .

**Scale-free network** In this study, we implemented a scale-free network using the following algorithm, known as the Barabasi-Albert (BA) model (Barabasi and Albert (1999)).

1. The algorithm begins with a single node.
2. Count  $k_i$ , where  $k_i$  represents the degree of node  $i$
3. Calculate  $P(k_i)$  by dividing  $k_i$  of each node by the sum of the degree of all nodes (Equation (3)).

$$P(k_i) = \frac{k_i + 1}{\sum_j (k_j + 1)} \quad (3)$$

4. Add a new node with  $m$  connections to existing nodes, on the basis of the probability of coupling  $P(k_i)$ .

Figure 4: Appearance of our snake-like robot with the muscles

5. Repeat steps 2-4 until a specified number of nodes is reached.

In the BA model, the number of connections to a single node in the network obeys the power law. Many real-world networks, such as the world wide web and human societal relationships, are known to be scale-free, and have been actively researched in recent years. Scale-free networks are also a type of small-world networks because of their structural characteristics. We have confirmed that the BA algorithm yields short average distance between two nodes, relative to the network size. Therefore, in a broad sense, we regard scale-free networks as small-world.

### Nonlinear oscillators

Our model adopts two types of nodes (nonlinear oscillators): output nodes, which directly connect to the body, and hidden nodes, which connect to each other with no direct connection to the body. Output nodes activate muscle fibers and receive feedback from length sensors of muscles, while hidden nodes affect the behavior of the model through the network. Each oscillator is represented as a boundary value problem (BVP) (Equation (??)) that behaves like the action potential of neurons. Multiple coupled BVPs are known to bifurcate (Equation (6)) and consequently display complex behaviors (Asai et al. (2000)).

There are two types of nodes (nonlinear oscillators) in our model. One of the types are output nodes, which have connections to the body directly, and another type are hidden nodes, which connected each other and have no direct connection to the body. Output nodes activate muscle fibers and receive feedback from length sensors. Hidden nodes affect the behavior of the model through the network. Each oscillator is represented by a BVP equation ((Equation (4)) and (Equation (5))) that behaves like the action potential of neurons. It is known that bifurcation occurs in multiple coupled BVPs (Equation (6)), which induce complex behaviors (Asai et al. (2000)).

$$\frac{dx_1[i]}{dt} = c(x_1[i] - \frac{x_1[i]^3}{3} - y_1[i] + z) + \delta(S_{other}[i] - x_1[i]) \quad (4)$$

Figure 5: Example of crawling movement by our snake-like body. Time series runs from right to left, and from top to bottom.

Figure 6: An example of bending movement by our snake-like body. Time series runs from right to left, and from top to bottom.

$$\frac{dy_1[i]}{dt} = \frac{1}{c}(x_1[i] - by_1[i] + a) + \epsilon S_{other}[i] \quad (5)$$

$$S_{other}[i] = \begin{cases} \sum_{j=1}^n \frac{C_{i,j}x_1[j]}{k[i]} & (HiddenNode) \\ \frac{1}{2}(gs_{in}[i] + \sum_{j=1}^n \frac{C_{i,j}x_1[j]}{k[i]}) & (OutputNode) \end{cases} \quad (6)$$

In the above expressions,  $x_i[i]$  and  $y_i[i]$  denote the action potential and inhibitory potential of node  $i$ , respectively, and  $z$  is the tonic input.  $S_{in}[i]$  is the sensor feedback from the muscle fibers, while  $g$  is the gain of sensor values.  $a, b, c, \epsilon, \delta$  are constants.  $k[i]$  is the degree of node  $i$ .  $C_{ij}$  is a weight matrix that represents the coupling state in the network. The tonic input controls the stability of oscillations; the higher the tonic input, the more chaotic the oscillators. The sensory gain controls the strength of connection between the musculoskeletal and oscillator systems.

### Network structures of nonlinear oscillators

Experiments were conducted on the following nonlinear oscillator networks.

**Experiment (a)** No connections among the nonlinear oscillators. Each oscillator connects to its corresponding muscle.

**Experiment (b.1)** Scale-free network, modeled by BA with no hidden nodes.

**Experiment (c.1)** One-dimensional lattice. Nonlinear oscillator network, modeled by the algorithm of Watts et al. with  $p = 0$ .

**Experiment (d.1)** Small-world network. Nonlinear oscillator network, modeled by the algorithm of Watts et al. with  $p = 0.01$ .

**Experiment (e.1)** Random network with no hidden nodes. Nonlinear oscillator network, modeled by the algorithm of Watts et al. with  $p = 1$ .

**Experiment (b.2)** Scale-free network, modeled by BA with 500 hidden nodes.

**Experiment (c.2)** One-dimensional lattice with 500 hidden nodes

**Experiment (d.2)** Small-world network with 500 hidden nodes.

**Experiment (e.2)** Random network with 500 hidden nodes.

To examine the effect of network size on the emergence of behaviors, we conducted experiments without hidden nodes and with 500 hidden nodes on all network models. Each connection weight was

Figure 7: Left: Conceptual diagram of the joint angle data at the time of behavioral transition. Right: An example of clustering of a trajectory in two principle components of the phase space, obtained by mean-shift clustering method. Each color represents a cluster. Finally, trivial clusters involving less than 10 % of the data points are eliminated from the estimated behavioral attractors.

Table 1: Average shortest distance between two nodes in each network with 500 hidden nodes

scale-free	one-dimensional lattice $p=0$	small-world $p=0.01$	random $p=1$
3.98	66.125	22.85	4.79

Table 2: Specifications of snake-like body

link of height	link of width	link of length	gap of two bodies	Mass of a link
0.1 [m]	0.1 [m]	0.1 [m]	0.02 [m]	0.6 [kg]
Number of links		Number of one joint muscles		Number of two joint muscles
15		0		26

randomly drawn from a uniform random distribution. The connection weights to each node were normalized to a norm of 1. Although the connections between nodes were bidirectional, the connection weights were determined independently for each direction. The degree distribution in networks with 500 hidden nodes is displayed in Figure 2. Table 1 shows the average distance between nodes in the networks.

### Snake-like body

The muscles of the snake-like body in our model are polyarticular, enabling more synchronous body movements (Niiyama et al. (2007)). Table 2 and 3 provide an overview of the snake-like body.

Simulations were performed using Open Dynamics Engine (ODE) Smith (2001). Our model consists of a set of nonlinear oscillators and the snake-like body. The nonlinear oscillators are separated into two categories: One comprises output nodes, which generate motor commands sent to muscles and receive the length sensor outputs from the muscles. Another comprises hidden nodes, which are not directly connected to the muscles.

## Experiments and Analyses

### Experimental settings

Experiments were conducted on the abovementioned networks. To examine the effects of the system parameters, we varied the tonic input and sensor gain parameter. For each parameter set, 100 experiments were performed with different randomized weights.

Figure 8: Number of behavioral attractors without any network structures

### Number of periodic motion patterns of the body

We estimated the number of periodic behaviors in the system by analyzing the time series of the robots joint angles, as described below.

1. Fourier-transform the series of joint angles over a shifting time window. In this study, the width of the time window is 5 [sec], shifting with a time step of 0.1 [sec]. After Fourier transformation, the frequency of maximum amplitude identifies the main component of the oscillatory behaviors in each joint. Accordingly, we refer to this wave of maximum amplitude as the representative wave.
2. Calculate the phases of the representative waves from the reference joint angle (Figure 7). Each point in the multidimensional phase space represents a single periodic movement.
3. For clustering, reduce the number of dimensions by principal component analysis. We selected five principle components, thereby retaining 90 % of the variance.
4. Estimate the number of periodic behaviors by applying mean-shift clustering (Comaniciu and Meer (2002)) to the data analyzed by principle component analysis.
5. Count the clusters. To reduce trivial behaviors, omit clusters containing fewer than 10 % of the data points.

Figure 9: Number of behavioral attractors with a scale-free network (hidden node:0)

Figure 11: Number of behavioral attractors with a small-world network (hidden nodes = 0)

Figure 10: Numbers of behavioral attractors with a scale-free network (hidden nodes = 500)

Figure 12: Number of behavioral attractors with a small-world network (hidden nodes = 500)

## Result

Figure 5 and 6 indicate time series of the robot movements. The robot mimics the motions of a natural snake. Throughout the experiments, the behaviors can be classified into a maximum of four movements: forward crawling (forward traveling waves), backward crawling (backward traveling waves), bending (stationary waves), and phase-shifted bending.

The average estimated behavioral attractors in Experiment (a) (no connections among the oscillators; one-to-one correspondence between oscillators and muscles) are shown in Figure 8 for different tonic inputs and sensor gains. The number of attractors is one for almost all parameter values. The results of Experiments (b.1) and (b.2) are shown in Figure 9 and 10, while those of Experiments (c.1) and (c.2) are shown in Figure 11 and 12, respectively. Distinct peaks appear in the landscapes of the estimated number of attractors in the networks of the parameter space. These results indicate that there are appropriate and inappropriate connectivity between networks and the body for versatile behaviors.

The effect of the sensor gain parameter was investigated at fixed tonic input 0.55. The results for networks without hidden nodes (Experiments (a), (b.1)-(e.1)) and containing 500 hidden nodes (Experiments (a), (b.2)-(e.2)) are shown in Figure 13 and Figure 14, respectively. Peak locations in networks generated by our algorithm and the Watts algorithm are identical, but differences exist between the networks themselves. Significant differences are

found among Experiments a, b.1, c.1, and d.1 (ANOVA, F-value = 4.635,  $p = 0.00391$ ), and among Experiments (a), (b.2), (c.2), and (d.2) at gain = 2 (ANOVA, F-value = 11.730,  $p = 5.68 \cdot 10^{-7}$ ). We consider that the scale-free nature of the network, rather than the average shortest distance between nodes, influences the movement behavior.

## Discussion

We examined several emergent behaviors resulting from interactions between different network structures, using nonlinear oscillators coupled to a musculoskeletal body. The behaviors of the models were diversified by the presence of complex network structures with optimal sensor gains. Because the number of periodic behaviors peaks around a certain sensor gain, we suggest that the interactions will be important to induce the most diverse behaviors.

Since bodily constraints induce stable periodic behaviors in Experiment (a), we consider the musculoskeletal body actuated by polyarticular muscles as an attractor of consistent behaviors. According to Jalan et al. (2005), oscillator complex networks dynamically generate diverse clusters. Therefore, for diverse behaviors to emerge, the combined dynamics of complex network and body must be well-matched. This consideration might be relevant to studies of the autistic brain and general movements.

Taga et al. (1999) identified a U shape development in healthy general movements. Using nonlinear prediction analysis, they re-

Figure 13: The number of behavioral attractors without a hidden network. Tonic input: 0.55

Figure 14: Numbers of behavioral attractors in the existence of each network with a network with 500 hidden nodes. Tonic input: 0.55

ported that movement complexity is high immediately following birth, decreases at around 2 months, and increases thereafter. The simulation results in this paper suggest that behavior becomes simpler when the dynamics are poorly matched, even if the nervous system is correctly characterized by a complex network. Developmental behavioral changes in human infants may manifest from matching of dynamics among the nervous system, the body and the ambient environment.

A recent MRI study found that the white matter in the brains of children with autistic spectrum disorder (ASD) is structurally different from that of their typically developing peers (Wolff et al. (2012); Courchesne et al. (2007)). Specifically, the brain tissue of ASD children displayed fewer long-range connectivities and stronger local connectivities. Motor development in premature infants who are later diagnosed as ASD is also atypical (Karmel et al. (2010)). Hadders-Algra (2008) proposed that the structural differences in the cerebral cortex of individuals with cerebral palsy and ASD cause reduced variability in motor behavior.

Can such structural differences explain the behavioral character-

istics of ASD, such as repetitive behaviors? From a complex systems perspective, repetitive behaviors in ASD may be regarded as a kind of stable state pulled into strong attractors within the dynamics of brain structure, body, and surrounding environment. Namely, an apparent relationship exists between complex cerebral networks and behavioral characteristics. Although we did not provide a direct treatment of this problem in this paper, we believe that our approach will yield theoretical insights into developmental disorders such as ASD.

## Conclusion

We modeled complex networks by nonlinear oscillators connected to a musculoskeletal body model, and conducted simulations in a range of scenarios. Diverse behaviors emerged in the combined network/body system under certain network structures and sensor gains. The results suggest that the network structure of human brains plays an important role in the emergence of diverse behaviors (such as general movements) in early human development. Future work will reveal fine differences between cerebral network structures and the whole body musculoskeletal system of fetuses and infants (Kuniyoshi and Sangawa (2006); Mori and Kuniyoshi (2010)). Such studies will significantly advance our understanding of human behavioral development.

## Abstract

We investigate the behaviour of the daisyworld model on an adaptive network, comparing it to previous studies on a fixed topology grid, and a fixed small-world (Newman-Watts (NW)) network. The adaptive networks eventually generate topologies with small-world effect behaving similarly to the NW model – and radically different from the grid world. Under the same parameter settings, static but complex patterns emerge in the grid world. In the NW model, we see the emergence of completely coherent periodic dominance. In the adaptive-topology world, the systems may transit through varied behaviours, but can self-organise to a small-world network structure with similar cyclic behaviour to the NW model.

## Introduction

In this paper, we examine connectivity changes in a complex adaptive ecosystem based on the daisyworld model, combining coupled map lattice (CML) and complex adaptive network models. Daisyworld, proposed by Watson and Lovelock (1983), is a simple mathematical system demonstrating planetary homeostasis – self-regulation of the environment by biota and self-sustainability of life through interaction with the environment. Daisyworld topologies in the literature are static, with only local connections (Wood et al., 2008). In our previous work (Punithan et al., 2011; Punithan and McKay, 2013), we have investigated ecological homeostasis in preconstructed static topologies with local and non-local long range couplings – small-world networks. But complex networks in nature and society are adaptive, in that they exhibit feedback between the local dynamics of nodes (state) and the evolution of the topological structure (Gross and Blasius, 2008; Gross and Sayama, 2009). Examples include genetic, neural, immunity, ecological, economic and social networks, complex game interactions etc.

The topology of our ecosystem evolves in response to local habitat states, and the evolved topology in turn impacts the habitat states. Our adaptive and self-maintaining ecosystem, based on CML consists of a set of diffusively coupled habitats incorporating logistic growth of life with bi-directional biota-environment influences. Thus our ecosystem incorporates three kinds of feedback:

1. Life-environment feedback via the daisyworld model
2. State-topology feedback via an adaptive network model
3. Density-growth feedback via a logistic growth model

The topology of the our ecosystem evolves with a simple local rule – a frozen habitat is reciprocally linked to an active habitat – and self-organises to complex topologies with small-world effect. In this paper, we focus on the emergent collective phenomena and properties that arise in egalitarian small-world ecosystems, constructed from a large number of interacting adaptively linked habitats.

## Background

Our model has three feedback loops determining its dynamics. We next detail the relevant background.

**Daisyworld (homeostatic self-regulation of the environment by the biota)** Daisyworld (Watson and Lovelock, 1983) is an imaginary planet where only two types of species live – black and white daisies. These biotic components interact stigmergically via an abiotic component – temperature. The different colours of the daisies influence the albedo (reflectivity) of the planet. In the beginning, the atmosphere of the daisyworld is cooler and only black daisies thrive as they absorb all the energy. As the black daisy population expands, it warms the planet. When it is too warm for black daisies to survive, white daisies start to bloom since they reflect all the energy back into space. As the white daisy cover spreads, it cools the planet. When it is too cold for the survival of white daisies, again black daisies thrive. This endless cycle, owing to the bi-directional feedback loop between life and the environment, self-regulates the temperature and thereby allows life to persist.

**Adaptive Networks (dynamics on the network interacting with dynamics of the network)** In most real-world networks, the topology itself is a dynamical system which changes in time and in response to the dynamics of the states of the nodes (dynamics of the network). The evolved topology in turn influences the dynamics of the states of the nodes

(dynamics *on* the network), creating a feedback loop between the dynamics of the nodes and the evolution of the topology. Networks exhibiting such a feedback loop (mutual evolution of structure and state values) are called adaptive or coevolutionary networks (Gross and Blasius, 2008; Gross and Sayama, 2009). In road networks, the topology of the road influences the traffic flow, while traffic congestion influences the construction of new roads. In the vascular system, the topology of the blood vessels controls blood flow, while restrictions in blood flow influence the formation of new arteries (arteriogenesis). Numerous other examples are discussed in Gross and Blasius (2008).

### Logistic Growth Model (density-dependent growth rate)

The discretised logistic growth model (Verhulst model) is key to population ecology.

$$P_{(t+1)} = P_t \left[ 1 + r \left( 1 - \frac{P_t}{\kappa} \right) \right]; \quad r > 0, \kappa > 0 \quad (1)$$

where  $P \in [0, \kappa]$  is the population size (at times  $t$  and  $t+1$ ),  $r$  is the intrinsic growth rate (bifurcation parameter),  $\kappa$  is the carrying capacity (maximum sustainable population beyond which  $P$  cannot increase). The parameter  $r$  amplifies population growth and the component  $[1 - \frac{P_t}{\kappa}]$  dampens the growth due to over crowding. Thus population density self-regulates population growth rate. It is also well-known that chaos emerges from this growth model (May, 1976) in spite of the built-in regulatory mechanism.

**Coupled Map Lattice** The coupled map lattice (Kaneko, 1985, 1992; Kaneko and Tsuda, 2001) incorporates discrete time evolution (map) in a discrete space (lattice or network) as in cellular automata (CA), but takes continuous state values as in partial differential equation (PDE) models. CML is governed by the temporal nonlinear reaction (maps -  $f$ ) and the spatial diffusion (coupling -  $\epsilon$ ).

If  $f(x)$  is a reaction function of a dynamical variable ( $x$ ), the update of the variable is computed by combining that reaction with discrete Laplacian diffusion. For a regular network with Moore neighbourhoods ( $k = 8$ ), the update of  $x$  is computed as:

$$\begin{aligned} x_{(i,j,t+1)} = f & \left( (1 - \epsilon)x_{(i,j,t)} + \frac{\epsilon}{8} \left[ x_{(i+1,j,t)} \right. \right. \\ & + x_{(i-1,j,t)} + x_{(i,j+1,t)} + x_{(i,j-1,t)} \\ & + x_{(i-1,j-1,t)} + x_{(i+1,j-1,t)} \\ & \left. \left. + x_{(i-1,j+1,t)} + x_{(i+1,j+1,t)} \right] \right) \end{aligned} \quad (2)$$

where  $x_{(i,j,t)}$  is the spatio-temporal distribution of a dynamical variable,  $\epsilon \in [0, 1]$  is the coupling parameter (diffusion rate),  $k$  is the number of interacting neighbours,  $f(x'_{(i,j,t)})$  is a local non-linear function and  $x'_{(i,j,t)}$  is the value after diffusion.

Denoting the set of neighbours of  $(i, j)$  as  $\langle l, m \rangle$ , we can simplify equation 2 to:

$$x_{(i,j,t+1)} = f \left( (1 - \epsilon)x_{(i,j,t)} + \frac{\epsilon}{k} \sum_{\langle l,m \rangle}^k x_{(l,m,t)} \right) \quad (3)$$

**Small-world Phenomena** The co-occurrence of high clustering (as in regular networks) and low characteristic path length (as in random networks) define a small-world structure (Watts and Strogatz, 1998). These small-world network properties, giving rise to the well-known “six degrees of separation” phenomenon (Milgram, 1967), are quantified by two statistical measures: the clustering co-efficient (measuring local cliquiness)  $\mathcal{C}$ , and the characteristic path length  $\mathcal{L}$  (measuring global connectedness). Their average values  $\bar{\mathcal{C}}$  and  $\bar{\mathcal{L}}$  for a network with  $n$  nodes are defined by:

$$\bar{\mathcal{C}} = \frac{1}{n} \sum_{v=1}^n \frac{|E(\Gamma_v)|}{\binom{k_v}{2}} \quad (4)$$

where  $\Gamma_v$  is the neighbourhood of a node  $v$ ,  $|E(\Gamma_v)|$  is the number of actual links in the neighbourhood of  $v$ ,  $k_v$  is the number of nodes in the subnetwork  $\Gamma_v$  and  $\binom{k_v}{2}$  is the number of possible links in  $\Gamma_v$ ; and

$$\bar{\mathcal{L}} = \frac{1}{\binom{n}{2}} \sum_{u=1}^n \sum_{v>u}^n d_{uv} \quad (5)$$

where  $d_{uv}$  is the shortest path between a pair of nodes  $u, v$ .

**Degree Distribution** The degree of a node is the number of neighbours it is connected to. The degree distribution is defined as the normalised frequency distribution of degrees over the whole network. The degree distribution of a network is a simple property which helps to classify networks. The regular network with Moore neighbourhoods have the same degree ( $k = 8$ ) for all the nodes. The degree distribution of small-world networks ( $p$  in the small-world regime (Punithan and McKay, 2013) follows a Poisson distribution with exponential tail. Networks in which most nodes have approximately the same number of neighbours are known as “egalitarian” networks (Buchanan, 2003).

## Model

Our ecosystem is a complex dynamic system in which the continuous state habitats diffusively interact with their neighbours (coupled), evolve in discrete time (map) and are distributed on a discrete space (lattice). Initially, we construct a 2-lattice with Moore neighbourhoods and periodic boundary conditions. Each point in the lattice represents a habitat with a maximum carrying capacity of 10,000 daisies. Each habitat in our ecosystem is a system. The elements

such as life (black and white daisies) and environment (temperature) are interconnected and interdependent via reinforcing and balancing feedback loops. At each succession of a habitat, we compute the population of black and white daisies, and the temperature, based on equation 3.

Table 1: Daisyworld Parameter Settings

Parameter	Value
Number of habitats ( $N \times N$ )	$100 \times 100$
Heat capacity ( $C$ ) $Wm^{-2}K^{-1}$	2500
Diffusion constant ( $D_T$ ) $Wm^{-2}K^{-1}$	500
Stefan-Boltzmann constant ( $\sigma_B$ ) $E^{-8}Wm^{-2}K^{-4}$	5.67
Luminosity ( $L$ )	1
Solar Insolation ( $S$ ) $Wm^{-2}$	864.65
Noise Level ( $K$ )	0.001
Opt. temp of black daisies $T_{opt_b}$ (K)	284.5
Opt. temp of white daisies $T_{opt_w}$ (K)	306.5
Carrying capacity ( $\kappa$ )	10000
Dispersion rate of daisies ( $D_c$ )	0.2
Natural rate of increase ( $r$ )	1

### Albedo:

The albedo ( $A$ ) at a lattice point  $(i, j)$  and at time  $(t)$  is

$$A_{(i,j,t)} = A_b(\alpha_b)_{(i,j,t)} + A_w(\alpha_w)_{(i,j,t)} + A_g(\alpha_g)_{(i,j,t)} \quad (6)$$

i.e. the average of the albedos  $A_b$  of ground covered by black daisies,  $A_w$  of ground covered by white daisies and  $A_g$  of bare ground, weighted by  $\alpha_b, \alpha_w, \alpha_g (= 1 - \alpha_w - \alpha_b) \in [0, 1]$ , the relative areas occupied by black, white daisies and bare ground at time  $t$ . We assume that  $A_w > A_g > A_b$ , with corresponding values of 0.75, 0.5, 0.25.

### Growth:

The growth curve of daisies ( $\beta_c$ ) is an inverted parabola:

$$\beta_c(T_{(i,j,t)}) = \max \left( 1 - \left[ \frac{(T_{opt_c} - T_{(i,j,t)})^2}{17.5^2} \right], 0 \right) \quad (7)$$

$T_{(i,j,t)}$  is the local temperature and  $T_{opt_c}$  is the optimal temperature of the species. The optimal temperature of the daisies depends on their petal colour 'c' (phenotype). The optimal temperature for black daisies is lower than for white; the mean optimal temperature is assumed to be 295.5K.

### Temperature:

The temperature ( $T_{(i,j,t+1)}$ ) is computed as the sum of temperature after Laplacian diffusion ( $T'_{(i,j,t)}$ ), the difference between solar absorption and heat radiation incorporating  $T'_{(i,j,t)}$ , and Gaussian white noise:

$$T_{(i,j,t+1)} = g \left( (1 - D)T_{(i,j,t)} + \frac{D}{k} \sum_{<l,m>} T_{(l,m,t)} \right) \quad (8)$$

where  $T_{(i,j,t)}$  is local temperature,  $<l, m>$  represents the set of neighbours of  $(i, j)$  and  $D = D_T/C$  is the thermal diffusion constant normalised by heat capacity  $C$ .  $g(T'_{(i,j,t)})$  is the temperature update function (Wood et al., 2008), in which  $T'_{(i,j,t)}$  is the temperature after diffusion:

$$g(T'_{(i,j,t)}) = T'_{(i,j,t)} + \xi + \left[ \frac{(SL(1 - A_{(i,j,t)}) - \sigma_B(T'_{(i,j,t)})^4)}{C} \right] \quad (9)$$

where  $S$  is the solar constant,  $L$  is the luminosity,  $A_{(i,j,t)}$  is the albedo,  $\sigma_B$  is the Stefan-Boltzmann constant and  $\xi$  is additive Gaussian white noise (with mean 0 and standard deviation 1.0) multiplied by the noise level (NL).

### Population size:

The local population update depends on dispersion, density-dependant growth rate and the feedback coefficient:

$$P_{c(i,j,t+1)} = h \left( (1 - D_c)P_{c(i,j,t)} + \frac{D_c}{k} \sum_{<l,m>} P_{c(l,m,t)} \right) \quad (10)$$

where  $P_{c(i,j,t)}$  is the population size at location  $(i, j)$  and time step  $t$ ,  $D_c$  is the fraction of the population being dispersed to its neighbours,  $c$  stands for colour of daisies and  $k$  is number of neighbours.  $h(P'_{c(i,j,t)})$  is the population growth function and  $P'_{c(i,j,t)}$  is population size after dispersion:

$$h(P'_{c(i,j,t)}) = P'_{c(i,j,t)} \left[ 1 + r \left( \beta_c(T_{(i,j,t)}) - \frac{P'_{c(i,j,t)}}{\kappa} \right) \right] \quad (11)$$

where  $r$  is population increase rate,  $\beta_c(T_{(i,j,t)})$  is the feedback due to temperature and  $\kappa$  is the carrying capacity.

### The Small-world Network Model

Small-world networks can be modelled in various ways – Watts and Strogatz (1998) (WS) model, Newman and Watts (1999) (NW) model, etc. Although the WS model was a breakthrough in network science, it may not guarantee connectivity owing to the rewiring process – deleting connections in the underlying network may result in disjoint nodes. Hence we use the later NW model, where we only add long-range connections. For each connection in the underlying ecosystem, a new reciprocal connection is added to a randomly chosen non-local habitat with probability  $p \in [0, 1]$ . In this work, we have chosen  $p = 0.05$ , since it is in the small-world regime and has proven to have interesting dynamics (Punithan and McKay, 2013).

## Adaptive Network Model

Adaptive networks are a class of dynamical networks whose topologies and states coevolve. Dynamic Linking (DL) is the key feature of adaptive networks, and can be modelled in a number of ways:

1. Active nodes grow and inactive nodes lose links
2. Active nodes lose links and inactive nodes grow them
3. Nodes never lose links; the network evolves by either:
  - (a) Adding new links to active nodes from inactive nodes
  - (b) Adding new links to inactive nodes from active nodes
  - (c) Adding reciprocal links between active and inactive nodes

By means of DL, we model the topology of our ecosystem itself as a dynamical system, changing in time according to a simple local rule (dynamics of networks). Each habitat, representing a dynamical system (dynamics on networks), is dynamically coupled according to the evolved topology. In our ecosystem, we never remove connections between habitats; we add new reciprocal connections between frozen habitats and active habitats (i.e. method 3c). This simple rule gives rise to a complex topology.

In our model, only black and white daisies disperse via both local and long-range connections, created either statically or dynamically (by water, air, animal pollinator transport etc.), while temperature diffuses only locally.

## Experiments

### Experiment Settings

The habitats are randomly initialised with a population size in  $[0, 100]$  for both species and with the temperature in  $[280, 310]K$ . We permit both species of daisies to coexist, hence we allow an overlap of 10% in the growth response to temperature. The overlap chosen determines the optimal temperature values of daisies. The parameter and their values are described in Table 1.

We have investigated daisyworld phenomenon in three different topological scenarios:

1. We start with an ecosystem where habitats are only locally connected (regular CML with Moore neighbourhood).
2. We add random non-local links to the underlying regular lattice, which introduces small-world effects in ecosystem (Newman-Watts model in CML)
3. Each frozen node in the underlying regular lattice is dynamically and reciprocally linked to a randomly chosen active node (adaptive CML).

A node is said to be frozen when its local dynamics are static – black and white daisies maintain the same population size

for six consecutive epochs. The links added either statically (NW) or dynamically (adaptive) are reciprocal links (mutual links). We ran 25 realisations of each network model, and present a typical example of a run of each model. Scenarios 1 and 2 were previously analysed in Punithan et al. (2011) and Punithan and McKay (2013), though with different overlaps (0% and 5%) respectively.

## Visualisations

We capture snapshots from the evolution of daisyworld to inspect its spatio-temporal dynamics. Each snapshot represents the population structure of the ecosystem at the particular epoch. As it is impractical to show all the snapshots over 5,000 epochs, we plot the temporal dynamics of daisy populations and temperature at a particular habitat as well as the temporal dynamics of the average daisy populations and temperature of the whole ecosystem. These plots reflect the behaviour of the daisyworld.

In the visualisations, a habitat is shown as black if black daisies alone occupy that habitat and correspondingly for white. If both daisies coexist at a habitat but black dominates, it is shown as dark grey; if white dominates, it is presented as light grey; and if the populations are equal, it is represented as medium grey.

## Results

### I. Daisyworld with Static Local Couplings (Regular Networks)

Figure 1: Regular CML:  $D = 0.2$  and  $NL = 0.001$  in 2D  $100 \times 100$

With only local couplings, we observe the formation of complex static patterns. The whole ecosystem freezes after epoch 1710. This scenario is clearly seen in the snapshots (Figure 1), in global population dynamics (Figure 4) and in global temperature dynamics (sub Figure 2 (b)). The local population dynamics (Figure 3) and local temperature (sub Figure 2 (a)) at a typical habitat (57, 50) shows that the dynamics freezes even quicker (epoch 1055). All trajectories show initial fluctuations but evolve to complete stationarity.

(a) Local Temp. at habitat (57, 50) (b) Global Surface Temp.

Figure 2: Regular CML: Temperature dynamics  $D = 0.2$  and  $NL = 0.001$

(a) Black Daisy Population (b) White Daisy Population

Figure 3: Regular CML: Local population dynamics at habitat (57, 50);  $D = 0.2$  and  $NL = 0.001$

(a) Black Daisy Abundance (b) White Daisy Abundance

Figure 4: Regular CML: Global population dynamics;  $D = 0.2$  and  $NL = 0.001$

## II. Daisyworld with Static Local and Non-local Couplings (Small-World Network)

Figure 5: Newman-Watts ( $p = 0.05$ ) :  $D = 0.2$  and  $NL = 0.001$  in 2D  $100 \times 100$  Small-world CML

(a) Local Temp. at habitat (52, 58) (b) Global Surface Temp.

Figure 6: Newman-Watts CML ( $p = 0.05$ ): Temperature dynamics  $D = 0.2$  and  $NL = 0.001$

(a) Black Daisy Population (b) White Daisy Population

Figure 7: Newman-Watts CML ( $p = 0.05$ ): Local population dynamics at habitat (52, 58);  $D = 0.2$  and  $NL = 0.001$

(a) Black Daisy Abundance (b) White Daisy Abundance

Figure 8: Newman-Watts CML ( $p = 0.05$ ): Global population dynamics;  $D = 0.2$  and  $NL = 0.001$

Each dynamic unit (habitat) is coupled through a small-world topology initialised through the NW mechanism. The topology remains static but the states of the habitats change dynamically. This ecosystem exhibits a periodic behaviour (Figure 5). The cyclic behaviour is understood by observing the trajectories in temperature dynamics (Figure 6), local population dynamics (Figure 7) and global population dynamics (Figure 8). This shows that a small change in the underlying topology drastically influences the dynamical properties of the ecosystem, and the transition is very abrupt. Within a single time frame, black dominance may change to white dominance, or vice versa (Figure 5).

## III. Daisyworld with Dynamic Local and Non-local Couplings (Adaptive Network)

The local dynamical linking rule (when a node becomes frozen, we allow that habitat to reciprocally connect to a random active habitat) generates topologies with small-world

Figure 9: Adapted Reciprocal Links

 Figure 10: Adaptive CML :  $D = 0.2$  and  $NL = 0.001$  in 2D  $100 \times 100$ 

effect (low characteristic path length (CP)) – here we show topologies with high clustering coefficient (CC) (approximately 50% of runs) to compare to NW-CML ( $p = 0.05$ ). It can also generate topologies with low CC. It depends on the random initialization of the temperature of each habitat and random dynamic linking. Typically we observe periodic behaviour (Figure 10) similar to NW-CML. In the corresponding time series plots, the dynamics of both local and global temperature (Figure 11), local population (Figure 12) and global population (Figure 13) exhibit cyclic behaviour. The dynamically adapted reciprocal links are shown in Figure 9.

### Why are NW-CML and adaptive CML similar?

Table 2: Typical Clustering Coefficients and Characteristic Path Lengths

Model	$\bar{C}/C_{\text{regular}}$	$\bar{L}/L_{\text{regular}}$
NW-CML	0.837	0.185
Adaptive CML	0.837	0.189

We saw very similar limit behaviours from NW-CML (Subsection II) and adaptive CML (Subsection III). We can gain understanding through analysing the topological quantifiers (degree distribution, clustering coefficient and characteristic path length) for their network topologies.

(a) Local Temp. at habitat (b) Global Surface Temp. (56, 57)

(a) Black Daisy Abundance (b) White Daisy Abundance

 Figure 13: Adaptive CML: Global population dynamics;  $D = 0.2$  and  $NL = 0.001$ 

Figure 14: Degree Distribution

The degree distribution of the small-world CML constructed via the NW model in sub section II ranges over  $[8, 14]$  and has an exponential tail reaching zero, as shown in the Figure 14(a). The degree distribution reached by adaptive CML in sub section III, which dynamically linked with reciprocal links, also ranges over  $[8, 14]$  and has an expo-

nential tail reaching zero as shown in the Figure 14(b).

The CC for NW-CML, and that for the final epoch of adaptive CML are almost the same, as are CPs. Figure 14 and Table 2 show the results. The finally-converged adaptive CML is an egalitarian small-world network. This is why we observe a drastic change in the dynamics of the system compared to the regular lattice. It also shows that the topology, constructed statically or dynamically, influences the collective behaviour of the system: relatively small changes in the linkage structure can generate vastly different dynamics.

Table 3: Average( $\pm$ Std.Dev.) Clustering Coefficients and Characteristic Path Lengths

Model	$\bar{C}/C_{\text{regular}}^-$	$\bar{L}/L_{\text{regular}}^-$
NW-CML	$0.8412 \pm 0.0024$	$0.1868 \pm 0.001$
Adaptive CML	$0.8928 \pm 0.0639$	$0.2204 \pm 0.0392$

The sections II and III illustrate typical scenarios of NW-CML and adaptive CML. Table 3 shows averages over 25 realisations of adaptive CML model and 25 of NW-CML ( $p = 0.05$ ) model. We ran 100 realizations of adaptive CML and picked 25 that fell in small-world regime (Punithan and McKay, 2013) for comparison purposes – CC in  $[0.98, 0.7]$  and CP in  $[0.3, 0.16]$ . CC and CP are normalised by the values for a regular lattice as proposed in Watts and Strogatz (1998).

## Topological Evolution

Table 4: Clustering Coefficients and Characteristic Path Lengths

Adaptation	$\bar{C}/C_{\text{regular}}^-$	$\bar{L}/L_{\text{regular}}^-$
Quick	0.977	0.295
Slow	0.837	0.238

The evolution of the topology continues until the stationary attractor (frozen local dynamics) of all habitats reach a dynamical attractor – here a limit cycle. Some samples adapt quickly, reaching a stable topology around the 500<sup>th</sup> epoch (Figure 15 (a) – Quick Adaptation), while a few evolve almost until the 5000<sup>th</sup> epoch (Figure 15 (b) – Slow Adaptation). Their degree distribution (Figure 16), clustering coefficient and characteristic path (Table 4) show that both evolve to small-world networks, although at different rates.

The collective dynamics in both quick and slow adaptations (Figures 18 and 19) show the shift in dominance is not so abrupt as in Figures 5 and 10 (see epoch nos.). The emergent property – the temperature cycles – depicted in Figure 17 (in both adaptations) have different limit ranges. In sub Figure 17 (b), the shift in dominance takes more time initially, eventually speeding up owing to the increasing limit height. The abruptness is clear in the corresponding global temperature plots – compare the limits in sub fig-

(a) Quick Adaptation

(b) Slow Adaptation

Figure 15: Adapted Reciprocal Links

(b) Slow Adaptation

Figure 16: Degree Distribution

(a) Quick Adaptation

(b) Slow Adaptation

Figure 17: Global Temperature dynamics  $D = 0.2$  and  $NL = 0.001$

ures 6 (b), 11 (b), 17 (a) and 17 (b). The degree distribution shows that relatively few reciprocal links are added (sub figure 16 (a)). This confirms even a few long-distance links – if they are the right links – lead to drastic behaviours changes.

## Conclusion

We have analysed the connectivity changes in a complex adaptive ecosystem combining life-environment, state-topology and density-growth feedback loops. The results illustrate the capacity of the adaptive ecosystem to self-organise to a complex ecosystem (small-world network)

Figure 18: Quick Adaptation :  $D = 0.2$  and  $NL = 0.001$  in 2D  $100 \times 100$

Figure 19: Slow Adaptation :  $D = 0.2$  and  $NL = 0.001$  in 2D  $100 \times 100$

through a simple dynamical rule – frozen habitats (nodes) gain reciprocal non-local neighbours (links). This ecosystem exhibits similar behaviour to contagion systems such as memes or virus – cyclic behaviours – without any external intervention, requiring only the adding of new reciprocal connections under certain locally-defined conditions.

Even a small change in the connectivity, with almost no effect on the mean degree of the ecosystem, leads to a drastic behaviour change from the grid network. It is much more like the real-world behaviour we see in social systems (seasonal rise and fall of fads), economic systems (booms and busts) etc.. This “small cause, large effect” behaviour draws analogies with popular metaphors black swan (low probable but high-impact events) (Taleb, 2010), butterfly effect (sensitive dependence on initial conditions) (Hilborn, 2004) and tipping point (little things make a big difference) (Gladwell, 2006). Though the collective dynamics change in varying ways, we still observe the emergent property – self-regulation of the temperature at around  $295.5K$ .

## Abstract

Biological organisms have the ability to develop novel phenotypes in response to environmental changes. When several traits are evolved simultaneously or as a result of one another, we talk of coevolution. Cellular Automata (CAs) have been successfully used to artificially evolve problem specific update functions. The resulting CAs are, however, much slower and more sensitive to perturbations than those with an evolved underlying topology and fixed uniform update rule. Unfortunately, these are not nearly as accurate, and suffer from scaling up the total number of cells. We propose a hybrid paradigm that simultaneously coevolves the supporting network and the update functions of CAs. The resulting systems combine the higher fitness and performance of the update evolution and the robustness properties and speed of the topology evolution CAs. Moreover, these systems seem to perform better as the size of the CA scales up, where as single-feature evolution systems are negatively impacted. Coevolution in CAs is an interesting tradeoff between the two single trait evolutions.

## Introduction

In biology, coevolution refers to the concurrent or sequential mutation in organisms driven by changes in a related biological object (Yip et al., 2008). Coevolution can occur at many different levels of biology: from populations and species, to adaptation of a predator to its (adapted) prey, to the evolution of a parasite/symbiont and its host, down to related mutations in amino-acids and proteins within a single organism. All members taking part in coevolution exert mutual selective pressure on each other, influencing the evolutionary process of the other. When taking place within a single biological entity, coevolution is beneficial to the entire organism. Multiple traits coevolve in order to produce individuals with a higher degree of “fitness” with respect to their environment. Cellular automata (CAs) have been used for years as a proxies for the simulation of rudimentary organisms and biological processes. In a prominent study, Mitchell *et al.* have successfully used genetic algorithms (GAs) to artificially evolve a single feature, the update function shared by all cells, of small radius one-dimensional CAs (Mitchell et al., 1993) to perform a prototypical task. However, tasks must not be only prototypical. CAs using GA

evolved functions have proven able to undertake complex tasks, applied, for instance to identifying combinations of genetic markers associated with clinical endpoints (Moore and Hahn, 2002b,a). More recently, we have conducted a study evolving a different property of CAs, the underlying network topology of CAs, with comparable success (Tomassini et al., 2005). The resulting evolved topologies are general graphs, which exhibit attributes of social network. A pioneering work by Sipper and Ruppert studied the coevolution of cellular machines (non-uniform CAs), now commonly known as (random) Boolean networks, which are non-uniform variants of the CA in which each cell has its own update function, instead of a single function shared by all cells (Sipper and Ruppert, 1997).

In this work, we propose a new framework for CA evolution consisting of the simultaneous evolution of the single update function shared by all cells (uniform CAs) and the supporting network topology of the CAs. We hypothesize that evolutionary algorithms (EAs) will generate individuals with a high capacity to solve the task at hand, and develop network topologies supporting speed, robustness, and resilience to transient failures better than that of strictly regular CAs (Tomassini et al., 2007). We compare the fitness-based performance of entire populations of the two single-feature artificial evolutions against a population of CAs simultaneously evolving both the update function and the layout of the cellular connections. Additionally, we analyze the scalability of both the existing frameworks and of the new one, as the performance of CAs with a relatively small fixed number of neighbors generally decreases with a larger number of cells. Finally, we conduct a statistical profiling of the artificially evolved network topologies in order to study the emergent properties of CAs with a higher performance.

## Background

### CAs and the Density Classification Task

CAs are dynamical, usually deterministic, discrete, abstract models used to simulate and study distributed computation. A standard CA consists of a finite number  $N$  of identical cells. Each cell can take one of a finite number of states  $s$ ,

here, the two Boolean states  $s \in \{0, 1\}$ . Each cell has a local knowledge of the state of a fixed number of  $n$  neighboring cells, including itself. The state of each cell is updated synchronously in discrete time steps, according to a local, identical update function or rule (these terms will be used interchangeably throughout this work) shared by all cells. Cells are usually arranged on a  $d$ -dimensional grid, where typically  $d \in \{1, 2, 3\}$ . In this study, we focus on one-dimensional, or linear CA, in which cells are arranged on a regular ring structure, connecting to a radius of  $r$  cells on each side. Thus the neighborhood size is  $n = 2r + 1$ . At any given *discrete time step*  $t$ , the set of all states  $s_i^t$  of all cells is called the *configuration* of the CA such that  $c^t = (s_0^t, s_1^t, \dots, s_{N-1}^t)$ , thus CAs with  $N$  nodes have exactly  $2^N$  possible configurations. Starting from an initial configuration (IC or  $c^0$ ) at time  $t = 0$ , the CA will travel across transient configurations before reaching a previously visited state of the system. After at most  $2^N$  time steps, the CA will start cycling deterministically through a subset of configurations.

**The Density Classification Task** The density classification task is a prototypical distributed computational task for CAs and is defined as follows. Let  $\rho_0$  be the fraction of 1s in the IC (i.e. time step 0). The CA's task is to determine whether  $\rho_0$  is greater than or less than  $1/2$ . If  $\rho_0 > 1/2$ , then the goal is to have the CA converge to a fixed-point configuration of all 1s; otherwise to a fixed-point configuration of all 0s, after a number of time steps with the order of  $N$ , where the CA has a odd size  $N$  to eliminate the case  $\rho_0 = 0.5$ . This computation is trivial for a computer having a central control and will provide the answer in  $O(N)$  time. However, it is nontrivial for one-dimensional CA, with a small radius, since such a CA can only transfer information at finite speed relying on local information exclusively, while density is a global property of the configuration of states (Mitchell et al., 1993).

## Graph Properties

A CA can be seen as a mathematical object known as a graph, where each cell resides on a vertex, and edges between vertices represent two neighboring cells. Therefore, formal definitions of graph theory do apply to CAs. For ease of reference, we summarize concepts used in subsequent sections particular to this work (see (Newman, 2010) for complete reference). In this work, a graph  $G$ , or network, consists of a set of  $v$  vertices  $V$ , and a set of  $e$  undirected, unweighted edges  $E$ . The degree  $k$  of a vertex is the number of edges connected to it. Thus the average degree  $\bar{k}$  of  $G$  is the average of the degree over  $V$ . A path between vertices  $u$  and  $v$  is defined as the sequence of unique edges traversed when going from  $u$  to  $v$ . Its length is the number of edges in the sequence. The average path length (APL) of  $G$  is the average length of the *shortest* path between all pairs of vertices.

The clustering coefficient  $C_j$  of a vertex  $j$  is defined as the ratio between the  $E_j$  edges that actually exist between the  $k_j$  neighbors of  $j$  and the number of possible edges between these nodes:  $C_j = 2E_j / (k_j(k_j - 1))$ . The clustering coefficient (CC) of a graph is defined as the average  $C_j$  across all vertices. The degree distribution  $P(k)$  of a graph  $G$  is a function that gives the probability that a randomly selected vertex has  $k$  edges incident to it.

## Artificial Evolution of CAs

It has been shown that the density task cannot be solved perfectly by a uniform, two-state CA with finite radius  $r < (N - 1)/2$  (Land and Belew, 1995). Despite the lack of a perfect solution, it is desirable to find one or more solutions that achieve the highest degree of performance possible.

**Evolving the Update Function** In general, it is extremely difficult to infer the local CA function that will give rise to the desired global computation due to possible nonlinearities and large-scale collective effects. On the other hand, exhaustive evaluation of all  $2^{2^n}$  possible functions is limited to small radii  $r \in \{1, 2\}$  by the computational cost. As first proposed by Mitchell *et al.* (Mitchell et al., 1994, 1993) for uniform CAs and by Sipper for nonuniform ones (Sipper, 1997; Sipper and Ruppin, 1997), EAs have proven to be a very effective heuristic to search in the colossal solution space of all update functions. Additionally, EAs have been applied to the discovery of efficient update functions for complex CA systems, such as CAs with multidimensional structure (Breukelaar and Bäck, 2005), as opposed to the linear, monodimensional nature of Mitchell's CAs, and those of interest in the present work.

**Evolving the Topology** In order to modify the underlying topology of the network supporting the cells, we will consider an extension of the concept of CAs. Therefore, cells can be connected in any way, provided that multiple edges are disallowed. Sipper and Ruppin have already examined the influence of different connectivity patterns on the density task. They studied the coevolution of network architectures and CA rules, resulting in non-uniform, high-performance networks (Sipper and Ruppin, 1997). More recently, Watts also moved away from regular structures, and hand constructed general uniform CAs for the density task (Watts, 1999). Because of the heterogeneous degree distribution of his networks, he had to reduce the update function to its simplest, and most flexible form, the majority rule (MR), to accommodate cells with varying neighborhood sizes. At each time step, each cell will assume the state of the majority of its neighbors in the graph. Watts built many networks with performance values exceeding that of CAs with evolved rules on regular lattices with similar average degree. Network structures yielding a good performance tend to have "long" links, creating shortcuts between distant

cells that somewhat compensate for the lack of information transmission of the regular lattice case.

In both these studies, the authors correctly recognized that reducing the average cell to cell distance, i.e. the APL, has a positive effect on the performance of the CA. Inspired by their work, we have explored the effect of artificially evolving the underlying topology of CAs with uniform MR starting with a population of regular lattice and one of random topology CAs (Tomassini et al., 2004, 2005, 2007). Evolved networks resulting from either initial populations tend to converge in the “small-world” region of the spectrum between regular structures and random ones (Watts and Strogatz, 1998). Indeed, these evolved topologies exhibited long reaching shortcuts across the network, thus significantly shortening the APL. Their CC is higher than that expected of equivalent random networks. Finally, their degree distribution was slightly skewed to the right, showing the emergence of a few higher-than-average connected hub cells, which is another property of social networks.

## Methods

In order to compare and contrast the performance of existing paradigms to that of our coevolution of topology and rules, we have implemented the two single-feature evolutions according to the original framework specifications. However, in order to make them comparable to each other and to our work, some parameters needed to be harmonized. Unless otherwise specified, parameters are identical across all simulation sets.

### Evolutionary Algorithm for CAs

In this work, we use an EA with the aim of evolving CAs for the density task. We assume the reader is familiar with the concept of artificial evolution, evolutionary computation, evolutionary algorithms, and genetic algorithms (Holland, 1975; Bäck, 1996; Mitchell, 1996). For all 100 experimental replicates, we generate an initial unstructured population of size  $P = 100$  individuals (i.e. individuals are not spatially limited in their interactions). The definition of individuals varies according to the framework used: update function, network topology, or both simultaneously (see below). We explore the scalability of the systems by studying CAs of size  $N \in \{99, 199, 299\}$ . Regardless of the size  $N$  and of the framework used, the initial population at generation  $g = 0$  is made of  $P$  uniform regular (i.e. ring) CAs with a radius  $r = 3$ , thus the neighborhood size of each cell is  $n = 7$ , including itself. The radius changes as the EA progresses when evolving the topology and with coevolution. Evolution is ended when the entire population has reached an optimal fitness, or after a maximum of  $g_m$  generations. We find experimentally that  $g_m = 100$  is enough for the populations to reach a *fitness plateau* where improvement becomes marginal or null.

The fitness function of the EA used to evaluate the “quality” of a CA individual in the population consists of experimentally evaluating the ability of the CA to solve the density task over a sample of 100 ICs with uniformly distributed densities  $\rho \in [0, 1]$ . CAs are allowed a maximum number of  $2N$  time steps to converge. If two consecutive configurations  $c^t$  and  $c^{t+1}$  are identical, the CA is stopped, as it has reached a *single configuration* attractor, and all consecutive configurations will remain identical. The fitness is defined as the fraction of instances (i.e. ICs) for which the CA produces the correct fixed point, given the known density of the IC. At each generation a different set of ICs is generated for each individual.

The next generation is obtained by repeating  $P$  standard *binary tournament* selection over the entire population. We describe the mutation methods below, as they depend on the evolution strategy. However, the mutation rates are selected quantitatively to yield the best results. The concept of *recombination* of network individuals is ill defined, and cumbersome to implement. However, we have used standard single-point recombination in frameworks that evolve the update function with a probability  $p_c = 0.25$ . At the end of each evolutionary process, we select the *elite population* (EP) by selecting the CAs that fall in the 95<sup>th</sup> percentile of *performance* (i.e. all individuals with a performance that is within the absolute best). For performance evaluation, the entire population is exposed to 1,000 instances of the most difficult problems possible, that is, on ICs with  $\rho \approx 0.5$ . Note the difference between *fitness* (100 uniform ICs) and *performance* (1'000 difficult ICs). In order to obtain statistically sound results, we replicate all experiments 100 times, and record the average fitness, the best fitness at each generation, and network statistics, such as the degree distribution, the APL and the average CC at the end of the evolutionary process.

**Evolution of the Update Function (UFE)** When we evolve the update function of uniform CAs with fixed topology, each individual of the initial population is assigned a different random update function in the form of a Boolean lookup table. This table is shared by all cells in the CA and its size is  $2^n$ , where  $n = 7$  is the size of the neighborhood. At each time step, cells synchronously update their binary state according to the state of their neighborhood. The ordering of the neighborhood is predetermined, thus making the system fully deterministic. At every generation, selected parent individuals will produce mutated offspring. The mutation will impact the offspring’s lookup table and is susceptible to change the binary value of each position in the table with a probability  $p_m = 5 \times 10^{-3}$ . The offspring will replace its weaker parent, if it has a better fitness than either. This approach is similar, although not entirely identical to that of Mitchell *et al.* (Mitchell et al., 1994, 1993).

**Evolution of the Topology (TE)** When evolving the topology, each regular uniform CA of the initial population is assigned the same update function, that is, the MR. At each time step, cells will update their state to reflect the majority of its neighborhood. As mentioned previously, the MR has been proven incapable of solving the density task when applied to a regular CA. In order to increase its fitness, we allow each CA to modify the structure of its supporting network. At every generation, selected individuals produce a mutated offspring that has a high probability of replacing its parent in the next generation if it shows a higher degree of fitness. Each cell will see its neighborhood mutated with a probability  $p_m = 5 \times 10^{-3}$ . If a cell is mutated, it will lose one of its neighbor or gain a random one with equal probability (Tomassini et al., 2005). This operator prevents drastic changes in the average degree of the CAs, which would giving an advantage to those with a higher connectivity (i.e. more edges). We disallow mutations that would produce self-loops or duplicate edges. In the case of a tie in an even sized neighborhood, the state will be drawn at random.

**Coevolution (CE)** This is the new framework we propose, allowing simultaneous evolution of the update function and the underlying topology of the network. Similar to the evolution of the update function only, coevolution starts with a population of uniform regular CAs, each with a randomly generated lookup table. As in the precedent frameworks, selected parents at each generation will produce mutated offspring, which may replace its parents in the subsequent generation. Mutations will now affect first the topology of the CA, by mutating edges with a probability  $p_t = 0.001$ , and then the lookup table, with probability  $p_r = 0.003$ . In this case, the size of the lookup table might need to be adapted to the growing sizes of the neighborhoods. Indeed, every time the size  $n_{max}$  of the largest neighborhood increases by 1, where  $n'_{max} = n_{max} + 1$ , the table size doubles, growing from  $2^{n_{max}}$  to  $2^{n_{max}+1} = 2^{n'_{max}}$ . The new half of the lookup table is completed with randomly selected values with equal probability. This ensures that, when the new neighbor is *off*, the target cell behaves just as it did before the new neighbor was added. When it is *on*, the target cell has a whole new behavior.

## Experimental Results

In order to compare results with previously proposed evolutionary CAs frameworks, we conducted parallel simulations for all possible combinations of frameworks (rule-only, topology-only, and coevolution) and sizes  $N \in \{99, 199, 299\}$ . At each generation of the artificial evolution, we record the average fitness of each population, and the fitness of the best individual. After the last generation has been produced, we segregate the EP as described above. We compute standard graph statistics on the CA networks of EP to shed some light on the mathematical properties that

set the evolutionary frameworks apart from one another.

## Performance and Fitness

The ultimate goal of evolving CA for computation, regardless of the framework, is to obtain individuals that excel at solving both the average case and the “worst case scenario” of the task at hand. In fact, a single individual is enough as long as its performance is satisfying the task’s criteria of quality and speed. Figure 1 shows the results of the performance evaluation of the EP on difficult problems. Each column represents a combination of frameworks and CA sizes. Performance, just like fitness, is on a scale from  $[0, 1]$  representing the fraction of correctly classified IC in at most  $2N$  time steps. We show the consistency of the EP results by showing the absolute best performance (upper mark), the average performance (horizontal line), and the lowest performance (lower mark). The number in parentheses is the size of the EP for each case, and gives an ideas of how rich the solution space is in “good individuals”.

Figure 1: Performance of Best Evolved CAs. Performance of all three frameworks: update function/rule evolution (UFE), topology evolution (TE), and coevolution (CE) of individuals  $N \in 99, 199, 299$  in the elite population (EP). Performance is measured over 1,000 ICs with  $\rho \approx 0.5$ . Average number of individuals in each run is in parentheses. In each column, the horizontal bar represents the average performance, the bottom mark represents the lowest performance, and the top mark shows the best performance. Results are averaged over 100 independent simulations.

In the case of smaller CAs, results across all frameworks are virtually undistinguishable, yet consistently above the 0.6 mark. In any case considered, the deviation between the maximum and the minimum fitness is minute ( $\sim 0.02$ ). The clear distinction comes with the scaling of the systems to larger CAs. The performance of TE CAs drops significantly as the system grows. Similarly, the UFE suffers a decrease of performance as the system grows, though not as much as TE CAs. On the other hand, coevolving CE systems see their performance remain stable or marginally improve as

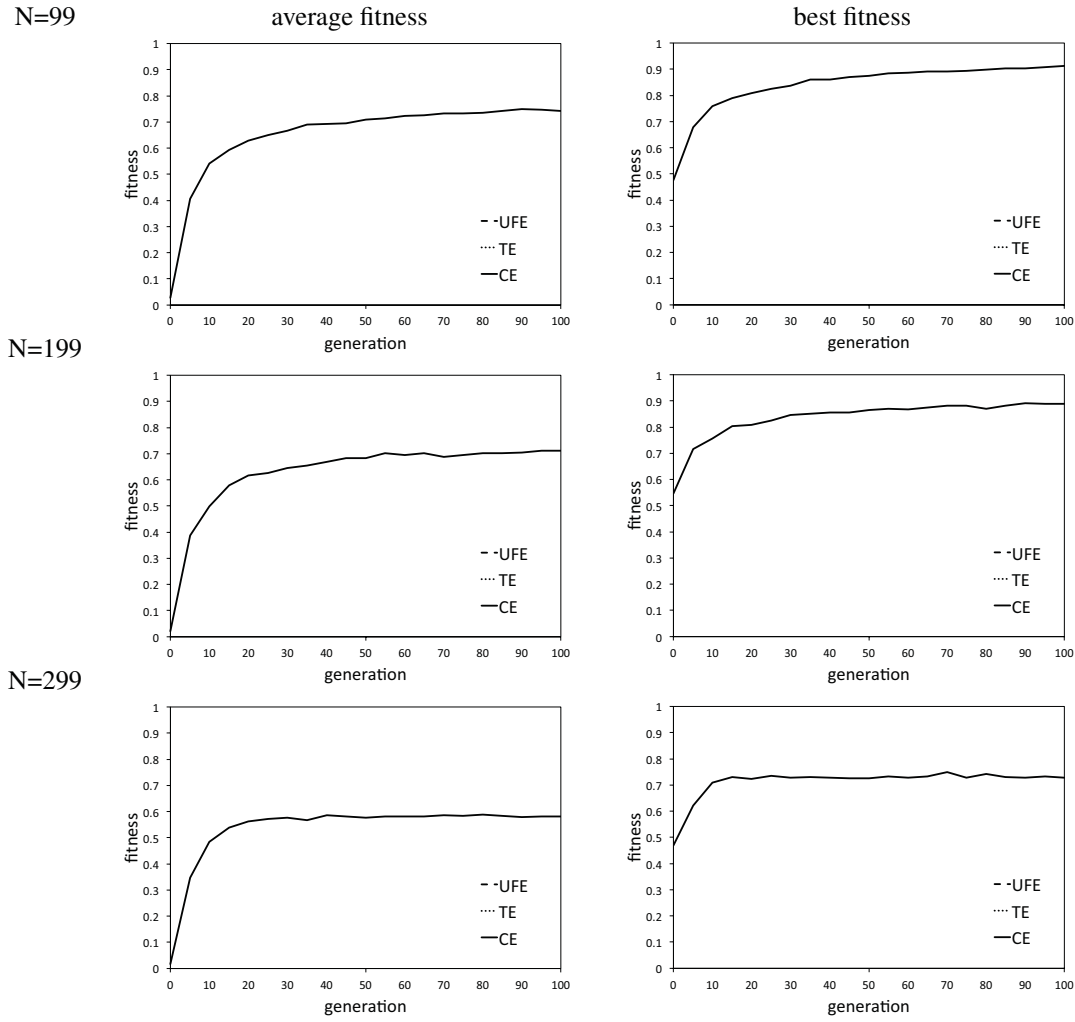

Figure 2: Fitness progression of Evolutionary CAs. Average fitness over the course of 100 generations for populations of evolutionary CAs (left column) and fitness of the best individual (right column). Systems of size  $N = 99$  (top row),  $N = 199$  (middle row), and  $N = 299$  (bottom row). Each panel shows results of all three frameworks: rule evolution (UFE, dashed line), topology evolution (TE, dotted line), and coevolution (CE, continuous line). Results are averaged over 100 independent simulations.

the CAs get larger. Interestingly, UFE and CE seem to consistently evolve a larger number of good individuals (Figure 1, numbers in parenthesis) than TE, therefore the solution space of TE is likely to be the poorest in EP CAs. This difference can be explained by the complexity and overall size of the actual solution space. In the case of UFE, there is at most  $2^{2^n}$  different update possible that constitutes the entire space. In the case of TE, however, the solution space is much larger, made of all possible topological network structures of  $N$  vertices. Surprisingly, the EP size of CE is also large, despite of the much larger solution space, made of all possible topologies coupled with all possible update function.

To understand the results presented above, we analyze the time progression of our evolutionary CAs over the 100 generations. We trace the development of UFE, TE, and CE

populations' average fitnesses in the left-hand column of Figure 2, whereas the right-hand side panels show the curves for the fitness of the best individual in the CA population, with the highest fitness value. Additionally, we show the scaling of these systems, which will also help us appreciate the shape and richness (or lack thereof) of the different solution spaces. When comparing the different combinations of evolutionary framework and sizes, we notice that the general trends are similar across all panels of a column in Figure 2. CAs under UFE and CE have the steepest learning curve. CE yield the second steepest curve, reaching a lower, CA size dependent, fitness plateau almost at the same time as UFE. The difference of average fitness between CE and UFE increases notably with the scaling in size  $N$ . However, we notice that this difference is less pronounced in the best

fitness curves in the right panels. This might explain the results in performance presented in Figure 1. The trace of TE has a different shape, with a slow start, turning into a steep slope, only reaching its fitness plateau consistently significantly higher than that of UFE or CE. Surprisingly, only the average population of TE seems impacted by the scaling. Additionally, in the average fitness panels, we note that the UFE and CE curves start at a fitness close to 0, where as TE starts with a lead of about 0.5, we note that the final fitness of TE is notably above that of UFE and CE, which seems to contradict the performance results above. In fact, we see the importance of the probability  $\rho$  of the ICs. Indeed, topology-only evolutionary CAs perform on average better than the other two on easier problems.

Best fitness results in the right-hand side panels of Figure 2 are consistent with those of the average fitness. Again, TE CAs reach a near optimum fitness, despite a slower start. The best individuals under UFE and CE preform closely, although UFE become clearly superior to CE with the increasing size of the system. Which again proves that the solution landscape of these EAs is not necessarily favorable to those rich in good individuals, as even randomly initialized individuals are capable of high fitness. Moreover, the fact that topology-only evolution yield a best fitness near 0.5 at the first generation also agrees with Mitchell's finding that uniform topologies with the majority rule cannot solve the density task better than a random system. The scaling of the CA sizes impacts the fitness of the coevolution framework the most, both in average and maximum fitness. We even witness a slight drop in best fitness for  $N = 199$ , a drop more prominent in  $N = 299$ , where after a slight, or no increase at all, the best fitness plateaus at a value lower than that of the maximum reached earlier in the evolution. We can only explain the fact that CE is detrimental for larger systems' fitness by the competing evolution of the two traits simultaneously. Nevertheless, the artificial evolution is beneficial in terms of producing CAs capable of consistently solving the task with any density  $\rho$ , especially those closest to  $\rho \approx 0.5$  and is clearest in the larger CAs. The results of UFE and TE are much more sensitive to the difficulty of the problem, where the fitness drops in both cases below the performance of CE in larger systems under difficult problems.

In summary, we note that the fitness in CE's may be less associated with performance than in the other models. This may indicate that high fitness does not (linearly) translate into high performance. It would appear that the TE's are the most flexible at solving the majority problem. While they may not be the best on the really hard problems, they show great adaptability to the a wide range of initial conditions.

### Properties of Evolved Topologies

EA's only goal is to optimize the performance of the CAs. However, looking beyond the fitness and performance, we are interested in studying the properties emerging from

the evolved topologies, and how they differ when obtained solely by topology evolution, and when the network's evolution is combined with adaptations of the update function. Therefore, we analyze the graph and statistical properties of the supporting network structure of CAs before the evolutionary process starts (i.e. a regular ring structure) and after the last generation of the EA. Figure 3 offers a visual representation of sample CA structures before (A) and after the evolution (B) and (C). Figure 3(A) shows the regular topol-

Figure 3: CA Topologies. Instances of a regular CA's initial network topology (A), and the CA topologies resulting from topology-only evolution (B) and coevolution (C). In the bottom row, the size of the vertices is proportional to the size of the neighborhood of the cell (i.e. degree of the cell). CA size  $N = 29$  for ease of reading.

ogy of UFE CAs (at all times) and of all CAs before the specific evolutionary process takes place. All vertices have a degree  $k = 4$ , and are thus all the same size. In the example graphs post-evolution (B) and (C), we see the emergence of cells of higher and lower degrees. The average degree of the networks is, however, maintained at all times  $\bar{k} \approx 4$  by the edge mutation within the graph (see Methods' section). The vertices' sizes are proportional to their degree, and ordered according to that criteria. At first glance, TE gives rise to a greater diversity in the vertices' degrees, whereas CE CAs seem more homogeneous in their degree distribution. The degree distributions of both frameworks, topology evolution and coevolution, and sizes of CAs are depicted in Figure 4. The values for the degree distributions are averaged over the elite population of the 100 replicates. From the degree distributions in Figure 4, we can see the EA has shifted the peak of the CE from all nodes having a degree  $k = 7$  to a majority of  $k = 8$ . Although there is some spread in the degrees, the function is narrowly centered around its peak, with little deviation, and no extreme values. TE has, on the other hand, facilitated a larger heterogeneity in the degree distribution, with a significantly wider bell shaped curve, and no clear peak at a single value of the degree  $k$ . TE CA networks has therefore more extreme values, where the minimum degree of a TE network is smaller than that of a CE network of the same size:  $k_{min}^{TE} < k_{min}^{CE}$ . The opposite is true of maximum degrees:  $k_{max}^{TE} > k_{max}^{CE}$ . The number of cells does not appear to have a marked influence on the shape of the degree distribution of emerging networks. The size of the CA only affects the magnitude of the function, not the shape. In Table 1, we report two essential statisti-

Figure 4: Degree Distributions of Evolved Topologies. CA topologies of sizes  $N \in 99, 199, 299$ . The degree distributions (bar plots) show the number of vertices (Y-axis) having a given degree (X-axis). Each panel contains the results for CAs with evolution of the topology-only (dark grey) and coevolution (light grey). Results are averaged over 100 independent simulations. Continuous lines are only meant as a guide for the eye to the trend of the degree distribution probability functions.

cal properties to the study of the CA topologies, the average path length and the average clustering coefficient after the evolution. Formal definitions of these two metrics can be found in the Background section.

The degree distributions in Figure 4 and the values of APL and CC in Table 1 suggest that the network structures emerging from artificial evolution share properties with technological, social, and other “real-world” networks. These architectures generally show greater resilience to perturbations than regular structures (Newman, 2010; Watts, 1999). Moreover, the even degree distributions, with a few hub-like cells, the short APL and higher CC of graphs after coevolution are all properties placing them even closer to “real-life” on the spectrum of all graphs.

### Speed of Convergence

If the quality of the results is key to the success of a CA, the speed at which the CA will converge to a solution is a non-negligible factor. In our previous studies (Tomassini et al., 2005, 2007), we show that the diffusion of information is immensely facilitated by the emergence of shortcuts across the networks, thus the shortening of the APL. Due to limited space, we present in Figure 5 only three examples representative of the ability of evolved-topology CAs to converge to a solution faster than regular CA, regardless of the excellence of their evolved rules.

In Figure 5, we show the progression of evolved CAs through the configuration space converging towards the correct IC density value. Mitchell *et al.* have analyzed the emerging patterns visible in this type of figure (Mitchell et al., 1993). In our results, TE CAs are consistently orders of magnitude faster than CE (over 500%), which are, in turn, significantly faster than UFE (10 – 300%) to reach a steady configuration.

### Conclusions & Future Work

Cellular Automata are, despite their apparent simplicity, powerful models for distributed computations, provided that

update function evolution (UFE)      topology evolution (TE)      coevolution (CE)

an adequate update function can be found. In the present work, we demonstrate once again the ability of EA to develop highly performant rules to solve a prototypical CA task, and remaining unaffected by the scaling of the CA size. The solution space is, in this case, rich in good solutions, making the EA capable of finding large numbers of functions that perform well. From a distributed computation perspective, the regular topology of standard CAs can be a weakness, as these structures are more susceptible to fail under transient perturbation. One alternative is to evolve the topology, and leave the majority rule as a constant update function. This TE paradigm evolves topologies showing properties of resilient systems, and the resulting CAs are a great deal faster than UFE. Unfortunately, their

performance is inversely proportional to the density, and to the size of the CA. In this work, we propose a framework that simultaneously evolves the update function and topology underlying. We have developed a novel update function implementation that integrates with the changing topology. The CAs resulting from CE demonstrate performance levels comparable to, and scale better than UFE, and are considerably faster. Moreover, the performance of CE systems remains constant (even slightly increases) as we scale up the size of the CAs. On the contrary, this scaling affects adversely the performance of both UFE and TE. Finally, they exhibit properties possibly making them even more robust network systems than TE CAs. We are planning on implementing a complementary study for structured populations, as they have been shown to increase the EA performance. In addition, we will conduct a thorough analysis of the resilience and fault tolerance of all evolved CAs (Tomassini et al., 2005).

# Bipartite Networks Show the Genotype-to-Phenotype Relationship in Biological Systems Models:

## A Study of the Robustness, Evolvability, and Accessibility in Linear Cellular Automata

### Abstract

In biological organisms, a single genotype may map to several phenotypes and vice-versa. This many-to-many relationship is believed to be a major drive of the phenotypic robustness and genotypic evolvability found in all life forms. Given the inherent complexity of the genotype-to-phenotype (G2P) mappings, we use cellular automata (CAs) as rudimentary proxies for biological organisms. CA models have the same many-to-many G2P mappings, and their sensitivity to initial conditions allows the same genotype to differentiate into different phenotypes. We use a bipartite network to study the G2P landscape, and its projections in either space. The degree distributions of the network and its projections are all *heavy-tailed*, denoting the presence of highly connected hubs, implying that increased robustness is supported by the network structure. We also show a strong correlation between the phenotype's complexity and its robustness. We analyze the relationships between the robustness and the evolvability both at the genotypic and phenotypic level. Although we use different computational models, our results agree with those of previous similar studies, and with observations in biological organisms.

### Introduction

For the past two decades, geneticists have been studying the intricate genotype-to-phenotype (G2P) relationship in biological organisms. Genome-wide association studies (GWAS), and the recent advances in modern high throughput sequencing technologies, have made understanding how metabolic reactions, cell signaling, and developmental pathways translate the genome of a living organism into its phenotype an achievable goal (Nuzhdin et al., 2012). However, GWAS have also unveiled unprecedented degrees of complexity, making clinical progress much slower than anticipated. As geneticists learn more about G2P mappings, it becomes more apparent that there is a many-to-many relationship. Indeed, several different genotypes, usually resulting from small perturbations or *neutral mutations*, result in the exact same phenotype. This feature is responsible for the phenotypic robustness of biological organisms, and their relative insensitivity to small genetic perturbations. On the other hand, identical genotypes may develop into dramatically different phenotypes, depending on a set of internal

and external signals and factors. The embryonic stem cell, which may potentially develop into any cell type, is a prime example of a single genotype yielding several phenotypes. The ability to adapt to internal and external factors is believed to be a major factor of the evolvability of all life forms. Given the inherent complexity of the G2P mappings, we recognize the need for smart, adaptive mathematical, statistical or computational models to study this relationship.

In this work, we use a cellular automata (CAs) model to exhaustively explore the G2P relationship in basic models of biological organisms. We are specifically interested in the nature of CAs, which in their simpler form mimic the many-to-many G2P relationship, and their sensitivity to initial conditions other model systems fail to encapsulate. CAs have been thoroughly studied in the past. However, in the context of this project, we will focus on the exhaustive description of all possible genotypes, phenotypes, and initial conditions. The results we gain from this are structured in a bipartite network, which consists of two types of nodes, in our case: genotype and phenotype. We then look at the projections of our bipartite network onto the genotype space and the phenotype space. Additionally, we study the distribution of robustness (also called neutrality) (Banzhaf et al., 1994) in the genotypic landscape of our model, and its effect on the phenotypic landscape. Similarly, we look at the genotypic and phenotypic evolvability, and the correlations between robustness and evolvability. Indeed, the seemingly contradictory effect of robustness and evolvability has been studied and disproved in many systems, where they in fact facilitate each other (Bloom et al., 2006; Ferrada and Wagner, 2008; Wagner, 2008a, 2005).

### Background

#### Cellular Automata (CAs)

CAs (Codd, 1968) are dynamical, usually deterministic, discrete, abstract models used to simulate and study distributed computation. A standard CA consists of a finite number  $N$  of identical cells. Each cell can take one of a finite number of states  $s$ , here, the two Boolean states  $s \in \{0, 1\}$ . Each cell has a local knowledge of the state of a fixed num-

ber of  $n$  neighboring cells, including itself. The state of each cell is updated synchronously in discrete time steps, according to a local, identical update function or rule (these terms will be used interchangeably throughout this work). In all CAs, update functions are generally represented as a Boolean lookup table of all possible binary permutations of the cell's neighborhood. Cells are usually arranged on a  $d$ -dimensional grid, where usually  $d \in \{1, 2, 3\}$ . In the present case of a one-dimensional, or linear CAs, cells are arranged on a regular ring structure, connecting to a radius of  $r$  cells on each side. Thus, the neighborhood size is  $n = 2r + 1$ . At any given *discrete time step*  $t$ , the ensemble of all states  $s_i^t$  of all cells is called the *configuration* of the CA such that  $c^t = (s_0^t, s_1^t, \dots, s_{N-1}^t)$ , thus CAs with  $N$  nodes have exactly  $2^N$  possible configurations. Starting from an initial configuration (IC or  $c^0$ ) at time  $t = 0$ , the CA will travel across transient configurations before reaching a previously visited state of the system. Because of its deterministic nature, the CA will, after at most  $2^N$  time steps, start cycling deterministically through a subset of configurations, called an *attractor*. Figure 1 shows a small example of a 8 cell regular uniform CA, set to a random IC.

Figure 1: Regular uniform CA. Size  $N = 8$ , with a radius  $r = 3$ , and set to a random (initial) configuration. Black cells represent state 1 and white is 0. Dashed edges “wrap around” to connect the CA into a ring topology.

**CA Genotype & Phenotype** CAs have been used for years as a rudimentary proxy for biological organisms and phenomena. One prevalent example, using a generalized form of CAs, is Kauffman’s Random Boolean Network (RBN) model for genetic regulatory networks (Kauffman, 1969). RBNs use non-uniform, unstructured CAs where each cell has its own Boolean update function (BUF) and can arbitrarily be connected to any other cell. Other models, such as Genetic Programming, Bayesian systems, or differential equations have also been thoroughly studied. CAs possess, however, a modest advantage. Indeed, CAs have a genotype, a phenotype, and mimic the many-to-many G2P mappings. The update function of CAs is a direct equivalent of a genotype, which can be mutated at will, and is a set of rules followed by the system to achieve a steady state. The attractor reached by the CAs is the phenotype resulting from a genotype and an initial configuration. The same attractor can be reached by different BUFs, and a single BUF can result in different attractors depending on the IC. In this work, we explore the evolvability, robustness, and accessibility of pseudo-biological organisms modeled by a small CA. We exhaustively explore all G2P mappings of a CA by repre-

senting it in a bipartite network, and also projecting it onto the phenotype and genotype landscape respectively.

Alternative methods have been used to map the G2P relationship, such as genetic programming Hu et al. (2011), and random Boolean networks Kauffman (1969). Moreover, one can imagine using almost any systems where a genotype and a phenotype can be described, for example NK-landscapes Kauffman and Weinberger (1989); Ochoa et al. (2008), and many more. However, we determined that CAs were the best suited tools to simulate the many-to-many G2P mappings, while keeping the analytical simplicity.

## Network Properties

A CA can be seen as a mathematical object known as a graph, where each cell resides on a vertex, and edges between vertices represent two neighboring cells. Therefore, formal definitions of graph theory do apply to CAs. For ease of reference, we summarize concepts used in subsequent sections particular to this work (see (Newman, 2010) for complete reference). In this work, a graph  $G$ , or network, consists of a set of  $v$  vertices  $V$ , and a set of  $e$  undirected, unweighted edges  $E$ . The degree  $k$  of a vertex is the number of edges connected to it. Thus the average degree  $\bar{k}$  of  $G$  is the average of the degree over  $V$ . A path between vertices  $u$  and  $v$  is defined as the sequence of unique edges traversed when going from  $u$  to  $v$ . Its length is the number of edges in the sequence. The average path length (APL) of  $G$  is the average length of the *shortest* path between all pairs of vertices. The clustering coefficient  $C_j$  of a vertex  $j$  is defined as the ratio between the  $E_j$  edges that actually exist between the  $k_j$  neighbors of  $j$  and the number of possible edges between these nodes:  $C_j = 2E_j / k_j(k_j - 1)$ . The clustering coefficient (CC) of a graph is the average of  $C_j$  over  $V$ .  $C$  is thus independent of  $N$  for a regular lattice, and approaches  $3/4$  as  $k$  increases. The degree distribution  $P(k)$  of a graph  $G$  is a function that gives the probability that a randomly selected vertex has  $k$  edges incident to it. For a random graph  $P(k)$  is a binomial peaked at  $P(k)$ . But most real networks do not show this kind of behavior. In particular, in scale-free graphs which are frequent in real-life,  $P(k)$  follows a power-law distribution.

**Bipartite Network** A bipartite network consists of two disjoint sets, or types, of nodes  $U$  and  $V$ . The nodes are connected in such a way that the nodes of one set will have no connections between them, but can only be connected to nodes of the other set. The use of a bipartite network is natural when dealing with two different types of data sets (see Figure 2b). Two nodes of the same type cannot be connected to each other, so one node can only be connected to a node of the other data type. We are interested in using a bipartite network to represent the relationship of our data.

From the bipartite network, one can project the data onto either the space  $U$  or  $V$  (Figure 2a,c). In either single dataset

Figure 2: Bipartite Network schematic. A bipartite network (b) made of two data sets the circles,  $U$ , and the rectangles,  $V$ . Projections in  $U$  (a) and in  $V$  (c).

space, the nodes are connected to one another “through” a vertex of the the other space. By ignoring the different types of data, all network properties described above remain valid on the bipartite network (as a single data set network) and on either projection. This type of network gives us three degree distributions, one for each projection, and one for the bipartite network. Each degree distribution shows how many links each node has. Nodes in a projection of a bipartite network are connected if they share at least one node in the other group. This gives us the ability to see the interactions within a group.

## Methods

In order to fully explore the G2P relationship in our CA model, we exhaustively explore all possible genotype mappings for all possible ICs. Unfortunately, the (super)exponential nature of the genotype and phenotype spaces, we are limited to a small number of cells,  $N = 5$ , and a *radius*  $r = 1$ , where the radius defines the number of neighbors each cell arranged on a ring can reach on either side. Therefore, a radius  $r = 1$  results in a neighborhood size of  $n = 3$ . In CAs, there are  $2^{2^n} = 2^{2^3} = 256$  possible genotypes. This is the limit, as the next possible regular neighborhood size being  $n = 5$ , which results in  $\approx 4.3 \times 10^9$  genotypes. This figure is computationally too expensive to search exhaustively. CAs have  $2^N = 2^5 = 32$  possible ICs, and the same number of possible point (i.e. single configuration) attractors, and at most  $2^{2^n} \times 2^N = 8192$  possible attractors of any length, as every combination of genotype and IC can potentially result in a different phenotype. We have successfully simulated CAs of size up to  $N = 12$ , the resulting networks are however not suited for representation.

Because we have two types of data, we can build a bipartite network. In our case, one set of nodes represents genotypes and the other, phenotypes. Our network is directed and shows the descent of a phenotype from a genotype. The degree distribution of the set of genotypes gives the number of phenotypes that are associated with each genotype and vice versa.

From our bipartite network, we can build the 2 other networks, one of each set of nodes. From this, we obtain a phenotype network and a genotype network. The nodes in each

of these networks are connected if, in the bipartite network, they share at least one node of the other type. For example, in our phenotype network, two nodes are connected if they share at least on genotype. We carry out the same process for the genotype network.

## Robustness, Evolvability, and Accessibility

Several measures of robustness and evolvability exist in the literature, at both the genotypic and phenotypic scales. Following (Wagner, 2008b), we define genotypic robustness as the fraction of the total number of possible point mutations to a given genotype that are neutral. Genotypic evolvability is defined as the fraction of the total number of possible phenotypes that are accessible through non-neutral point mutations to a single genotype. Phenotypic robustness is defined as the size of the phenotype’s underlying genotype network. For phenotypic evolvability, the proportion of the total number of phenotypes that can be reached via non-neutral point mutations from a given phenotype.

In addition to measuring the propensity to mutate away from a phenotype, we also measure phenotypic accessibility (Cowperthwaite et al., 2008), denoted by  $A$ , which is formally defined as:

$$A_i = \sum_j f_{ij},$$

where

$$f_{ij} = \begin{cases} \frac{v_{ij}}{\sum_{k \neq i} v_{ik}}, & \text{if } i \neq j \\ 0, & \text{if } i = j \end{cases}$$

This metric takes on high values if phenotype  $i$  is relatively easy to access from other phenotypes, and low values otherwise.

## Results

This section describes the analyses resulting from the exhaustive simulation of the G2P relationship under all possible initial conditions in a small CA. We begin by describing the G2P spaces in the form of its bipartite network and its projections, and studying the networks’ statistical properties. The second part of this section focuses on the correlations between the genotypic and phenotypic robustness, evolvability, and accessibility.

### Bipartite Network of G2P

We start by representing the G2P relationship in our CA model as a bipartite network. Figure 3 represents this bipartite network, the degree distributions, and both projections. Figure 3a shows the bipartite network, where genotypes (on top) only connect to phenotypes (on the bottom). To the best of our knowledge, this is a novel perspective on representing the G2P mappings. In all network Figures 3a-c-d, the size of the vertex is proportional to the number of members of

the opposite dataset associated. In other words, the genotypes vertices are proportional to the number of phenotypes mapped, and vice-versa. For readability reasons, we have filtered out vertices of a degree below 5. In the same figure, we also show the trends of degree distributions for the bipartite network, as well as both projections of the genotypes only and of the phenotypes only.

We identify the two most evolved phenotypes as the two single-point homogeneous phenotypes (00000 and 11111). The next most evolved phenotype is a two-state attractor made from the previous two. As expected, the identity update function (01010101) is the genotype that maps to the most phenotypes. In Figure 3b, all degree distributions are right skewed, with a heavy tail, denoting the presence of highly connected “hub” vertices and a “scale-free” like topology. In other words, the degree distribution of the network decays like a power-law or exponential function.

Beyond the degree distributions, we are also interested in showing a few more statistical characteristics of the networks, and how they differ between the bipartite network and the projections. Table 1 summarizes these measurements, described in the Methods Section.

network	bipartite	genotype	phenotype
#vertices	395	256	139
#edges	1398	1024	1268
$\bar{k}$	3.539	8.0	18.245
CC	0	0	0.816
APL	1	4.016	2.102

Table 1: Networks statistics for the bipartite network as a whole, and both the projection on the genotypes space and on the phenotypes space.

As we can see in Table 1, the bipartite network regroups all genotypes and phenotypes. Interestingly, we note that our networks are generally dense, with high  $\bar{k}$  in the projections. In addition, we show that there is no clustering structure to speak of in the genotype network, and that the phenotype network is highly clustered. Finally, the phenotype network has a short APL. The high CC and the short APL of the phenotype network hints at interesting community properties in the phenotypes, which clusters phenotypes that are densely connected in subsets that share common biological or genetic information. This finding is in line with a previous, much more applied study on the Human Phenotype Network (HPN). In Darabos et al. (2013), we report that the HPN does have a strong community structure, and we are now reassured to note that the CA model phenotype network shares this characteristic.

### Robustness, Evolvability, and Accessibility

In this section, we analyze the complex relationships between robustness and evolvability, both genotypic and phe-

notypic. We also report results of the influence of phenotypic accessibility. These links are, we believe, the most biologically relevant and could confer the most relevance to our model. In order to conduct this analysis, we study the statistical characteristics of the genotype and phenotype spaces, assigning robustness, evolvability, and accessibility “scores” to each genotype and phenotype, according to the description found in the Methods Section.

Firstly, we report in Figure 4 the strong, quasi linear positive correlation between the number of phenotypes mapping to a genotype, and the evolvability of those genotypes. This correlation is to be intuitively expected from biological organisms in which genotypes responsible for more phenotypes are also considered the most evolvable.

Figure 4: Strong correlation between the number of phenotypes mapped from a genotype and the genotypic evolvability.

One interesting aspect of robustness and evolvability in all systems, is their relationship to the perceived complexity of the phenotype. In our case, the complexity of the phenotype is measured by the size (or length) of the attractor. These relationships are depicted in Figure 5.

In Figure 5, we report a strong negative correlation between the length of the phenotype’s attractor and its robustness. This result agrees with Kauffman’s work on RBNs (Kauffman, 1969), who early on has reported that longer attractors are less stable in RBN systems. The same negative correlation appears with phenotypic evolvability. We speculate that more complex phenotypes have more difficulties accessing other phenotypes because of the basin of the attraction size. This is confirmed by the fact that more robust phenotypes are also less accessible (see below, Figure 7d).

We are especially interested in genetic robustness and evolvability and how they are distributed over the entire genotype space. These results are reported in Figure 6a-b. Moreover, we study the relationship between genetic robustness and evolvability in Figure 6c.

The “bell shaped” distributions of genotypic and phenotypic robustness (not shown here), or neutrality, are also aligned with results in similar studies (Hu et al., 2011). Most

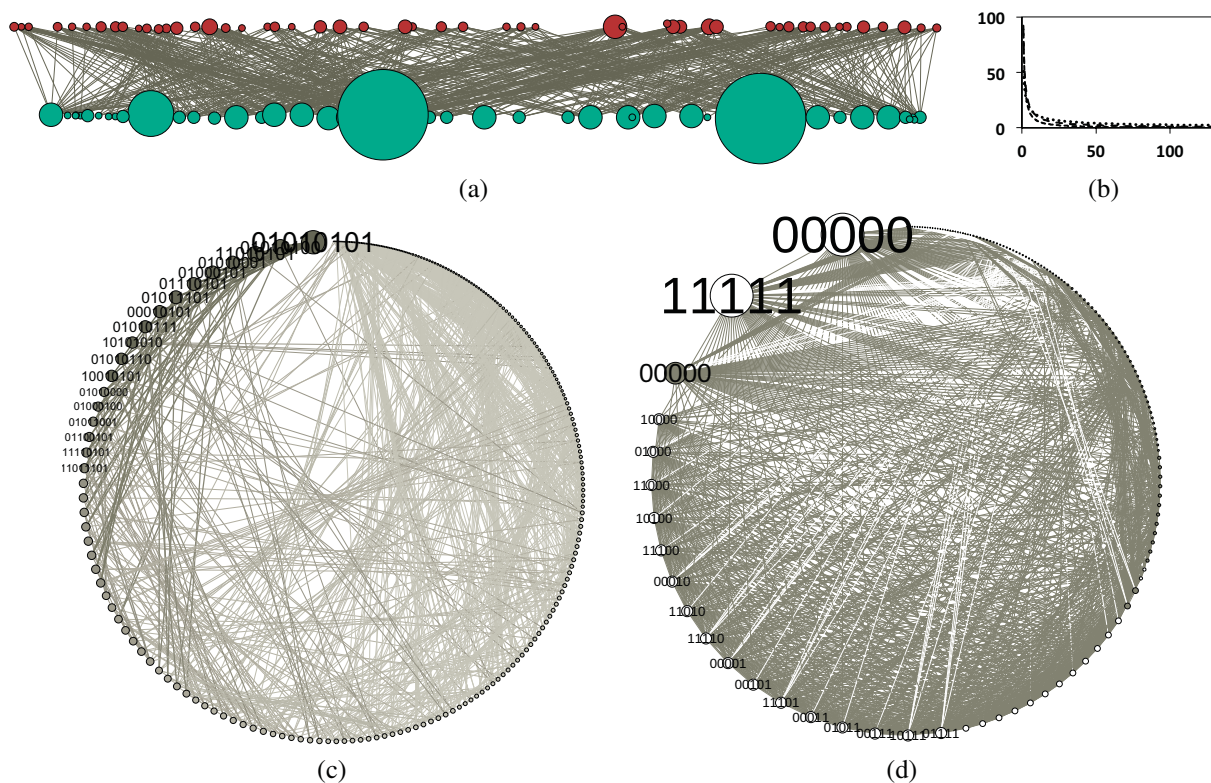

Figure 3: Filtered Bipartite G2P Network, Degree Distributions, and Projections. (a) The top row vertices represent the genotypes, and the bottom row vertices represent the mapped phenotypes. The vertex size is proportional to the degree (i.e. to the number of mapped phenotypes, or mapping genotypes respectively) Vertices of a degree below five are omitted for readability reasons. (b) the “heavy-tailed” degree distribution for the bipartite network and both phenotype and genotype projections. (c) the projection in the genotype space, the vertex sizes are proportional to the number of associated phenotypes, the darker the edge, the more phenotypes the genotypes have in common. (d) the projection in the phenotype space, with vertex sizes proportional to the number of mapping genotypes. The vertex is white if the phenotype is a point attractor, and grey if the attractor is longer (i.e. the phenotype is more complex). The darker the edge, the more genotypes the phenotypes have in common.

genotypes have a high robustness, and a rather low evolvability. However, the genetic evolvability distribution is right-skewed, with a heavy tail, therefore, a small number of genotypes have a very high evolvability. Interestingly, genotypes which have a middle range value robustness ( $\approx 0.5$ ) tend to show a higher degree of evolvability. In other words, high or low genetic robustness yield lower evolvability than mid-range values.

Relating this research to biological organisms, we are particularly interested in the phenotypic aspect of the CA models and how they respond to external (i.e. environmental) and internal (i.e. genotypic) perturbations, and how these perturbations impact robustness. Therefore, we consider the phenotypic robustness of our systems, and study its relationships to genotypic and phenotypic evolvability, genotypic robustness, and the accessibility of the phenotypes. These results are reported in Figure 7.

The first, and natural correlation we are interested in is phenotypic robustness to evolvability. Figure 7a shows a

strong correlation between phenotypic robustness and evolvability. This means that phenotypes that are more robust are also more evolvable, and vice-versa. Although it seems counterintuitive that more stable phenotypes are also more evolvable, our findings are in perfect agreement with Wagner’s conjecture and work, in which stability in biological organisms actually supports evolvability (Wagner, 2008b). In Figure 7b, we see that more robust genotypes do not give rise to more robust phenotypes, and vice-versa. This is not actually surprising, although it is not in line with Hu’s work (Hu et al., 2011). In our work, the robustness of the genotype does not guarantee that of the phenotype. Panel (c) shows that phenotypic robustness and genotypic evolvability are moderately negatively correlated, which indicates that more stable phenotypes are obtained by genotypes that can give rise to fewer phenotypes after a small perturbation. Finally, Figure 7d reveals that phenotypes that are the least accessible from other phenotypes, through small mutation of their genotypes, are also the most stable. This implies that ran-

Figure 7: Phenotypic Robustness in relationship to (a) genotypic evolvability ( $r = -0.46$ ), (b) genotypic robustness ( $r = -0.02$ ), (c) phenotypic evolvability ( $r = 0.79$ ), and (d) phenotypic accessibility ( $r = -0.37$ ). We show trend lines on all panels and specify the correlation coefficients ( $r$ ) in parenthesis.

dom mutations are less likely to lead to robust phenotypes than to non-robust phenotypes. Combining the observations in panels (a) and (d), we hypothesize that the most robust phenotypes are difficult to find (Figure 7d) and highly evolvable (Figure 7a).

## Conclusions

In order to explore the complex genotypes-to-phenotypes (G2P) relationship in biological organisms, we propose to use small, simplistic, proxies in the form of a Cellular Automata (CAs) model. CAs share the many-to-many G2P mappings of living organisms. In this implementation, we keep the systems small enough so that we can exhaustively explore both the genotype and the phenotype space, and all initial conditions. To visually assess the G2P associations, we use a bipartite network and its projections onto either space. It shows a dense network, with some prominent genotypes that can access all phenotypes, and some highly popular phenotypes that can be reached by all genotypes.

Genotypes that are associated with the most phenotypes are also the most evolvable, which suggests that evolvable genotypes cluster together and tend to be genetically close. In agreement with Kauffman's work on RBNs, the phenotype's complexity (i.e. attractor length) is negatively correlated with both its evolvability and its robustness. In addition, we conclude that the more evolvable genotypes yield

a robustness in the middle of the range of possible values. These results suggest that some robustness is necessary to promote evolvability in genotypes, but too much robustness will hinder genotypic evolvability.

Finally, we showed that phenotypic robustness and evolvability are closely related, which agrees with Wagner's results, and that phenotypic robustness supports phenotypic evolvability. Despite its counterintuitive nature, this finding is aligned with biological systems. We also see that stable phenotypes are not generated by stable or evolvable genotypes. Moreover, we note that popular (accessible) phenotypes tend to be less robust, which contradicts some evidence in natural systems.

Robustness, evolvability and accessibility correlations, or lack thereof, are highly system-dependent. In the case of CAs, we show that these relationships are, generally, in line with observations in biological organisms. However, the robustness-evolvability-accessibility relationship in biological organisms is also highly system-dependent. Nevertheless, models are unavoidable when studying interactions as complex as G2P, and CAs remain a viable option, considering that they also model the many-to-many G2P relationship.

In a future line of research, we plan on exploring the G2P relationships in much larger CAs in order to inch closer to simple biological organisms. Unfortunately, this will come

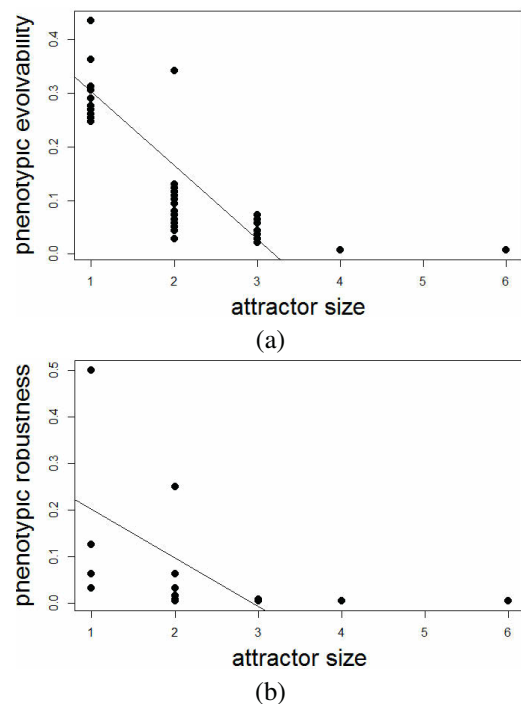

Figure 5: The effect of Attractor size on (a) phenotypic evolvability ( $r = -0.74$ ) and (b) phenotypic robustness ( $r = -0.39$ ). We show trend lines on all panels and specify correlation coefficients ( $r$ ) in parenthesis.

at the cost of the exhaustive search, and force us to select a limited number of sample genotypes and phenotypes mappings. Moreover, we are planning on addressing the phenotypic plasticity, or adaptability of the phenotype during its lifetime, and explore ways to integrate this aspect into our CA model without losing its attractive simplicity. Finally, it would be interesting to compare our results with a real-life biological case, if the quality of the data permits.

# The Effects of Assortment on Population Structuring Traits on the Evolution of Cooperation

Adam Jackson<sup>1</sup> and Richard Watson<sup>1</sup>

aj3e10@soton.ac.uk

## Abstract

Population structure plays an important role in the evolution of social behaviours, particularly by generating positive assortment on social interactions. This enables cooperative behaviours that have a net cost to the individual to spread by directing their benefits towards other cooperators. Previous work on the coevolution of population structures and social behaviours has suggested that the evolution of population structuring traits is strongly influenced by the dominant social strategies. Here we investigate the idea that the coevolution of population structure and behaviour can be enhanced in favour of cooperation when there is also assortment on the population structuring traits themselves. This paper presents a simulation model that investigates the effects of evolving this second-order assortment and introduces a mathematical framework to model it in terms of the replicator equation. We find that with second order assortment the dominant social behaviour trait does not necessarily have to control the evolution of population structure, increasing the range of social scenarios in which population structures that support increased cooperation can evolve.

## Introduction

Population structures that promote positive assortment on social behaviours are a key pathway to the evolution of cooperation (Nowak and May, 1992). When cooperators interact disproportionately with other cooperators then the benefits of the cooperative acts will fall predominantly on cooperators, raising their fitness while reducing the risk of defectors taking the benefits without assuming the costs. There are many mechanisms that can support the evolution of cooperation, including genetic relatedness, signalling (greenbeard effects) and reciprocity through repeated interactions. The common principle at work is that these mechanisms generate correlated interactions by co-operators (Godfrey-Smith, 2009). Only when the benefits of cooperation are directed at other cooperators in this way can cooperative behaviours that benefit the recipient at a cost to the individual spread (Hamilton, 1964; Lehmann and Keller, 2006).

This is important both to explain the otherwise surprising ubiquity of cooperative behaviours and because of the underlying importance of altruism to the major transitions in

evolution, the processes through which new levels of biological organisation emerge as previously independently replicating entities become higher-order individuals that must reproduce as a unit (Maynard Smith and Szathmáry, 1997). The altruistic sacrifice of individual reproductive capability at the lower level is such a characteristic of this process that the major transitions can be viewed as extreme examples of social integration (Michod, 2000; Queller and Strassmann, 2009; Bourke, 2011).

Traditionally social evolution models have investigated the evolution of cooperation against a fixed population structure. But many organisms possess individual-level genetic traits that affect population structure, such as a group size preferences or dispersal radius (Pepper and Smuts, 2002). Recent work has begun to look at how population structuring traits and social behaviours can coevolve in a process of *social niche construction* (Powers et al., 2011). Artificial Life models of the coevolution of group size preferences and social behaviours have shown that linkage disequilibrium develops connecting a preference for small groups with cooperative social traits (Powers and Watson, 2011). In such circumstances between group effects can outweigh within group competition due to the high variance between groups, caused by sampling small groups from a large population (Wilson and Colwell, 1981), leading to a positive feedback loop in favour of increasing levels of cooperation and decreasing group size even when the social game is unfavourable to co-operators.

It is generally well accepted then that positive assortment can enable cooperation to prevail when it would not in a well-mixed population. In previous work we have been investigating the factors that lead population-structuring traits to support the evolution of cooperation using evolutionary game theory. Many changes in population structure can be represented as transformations to the social game being played, including reciprocity, kin selection (Taylor and Nowak, 2007) and group structure (Van Veelen, 2011). We have looked at the coevolution of population structures and social behaviours through abstract models of *metagames* in which populations evolve not just their social behaviours but

also the payoff matrix of the game they are playing. These metagame models have demonstrated that the strongest influence on the selective pressure on the population structure is the dominant social strategy; when co-operators are the dominant social type population structures more favourable to cooperation evolve, and likewise when defectors dominate. This is in apparent contradiction with the logical arguments that support social niche construction (Powers et al., 2011), and would imply a limited causal significance for population-structuring traits if they only increase the spread of cooperative behaviours in situations where co-operators are already favoured.

Here we suggest that one of the keys to the strength of social niche construction is that not only do population-structuring traits (*PSTs*) induce assortment on the social behavioural traits but that there is also a degree of assortment on the *PSTs* — a *second order assortment*. In the example of a group size preference trait, if the group size preference leads to a greater chance of living in a group of the desired size it also implicitly creates groups composed of individuals with similar group size preferences (Powers et al., 2011). Not all population-structuring traits do result in second-order assortment. It is argued that the key distinction between kin-selection and greenbeard traits is that relatedness leads to the same average measure of correlation for all the genes of an organism while greenbeard traits only lead to correlation on a few genes (Ridley and Grafen, 1981; Bourke, 2011). As a consequence greenbeard traits may be susceptible to parasitism (Okasha, 2002) and intragenomic conflict — suppressor mutations arising at other *loci* (though others have argued that this is not inevitable as selection for greenbeard and greenbeard-imitation traits may be aligned (Gardner and West, 2010; Biernaskie et al., 2011)). So we might expect that when assortment is generated by relatedness there would be the same degree of assortment on population-structuring and behavioural traits, while if it was generated by a greenbeard signal this is not necessarily the case.

In this paper then we investigate the effects of second-order assortment on the evolution of population-structuring traits that support cooperation, in particular the nature of the second-order assortment. We do this through an artificial life model in which different levels of assortment are expressed literally — assorters are physically more likely to interact with each other. We also develop a novel way to model these results mathematically by modifying the replicator equation. We show that when second-order assortment is random or absent then the spread of population-structuring traits that support increased cooperation is strongly linked to the success of co-operators. When population-structuring traits affect both assortment on social behaviours and on themselves, then the conditions under which populations can evolve population structures beneficial to cooperation are enlarged.

## Social Dilemmas in Evolutionary Game Theory

The standard mathematical tool for analysing the evolution of social behaviours is evolutionary game theory (Maynard Smith, 1982). Evolutionary game theoretic models are appropriate when the fitness of a strategy depends on the frequency with which it and other strategies are found in the population as well as the inherent qualities of the strategy — as is the case for social behaviours. There are a number of ways to interpret game theoretic models; here we think of a population divided into a  $n$  genetically determined types corresponding to pure strategies of the game. The fitness payoffs for the interactions between types determines the payoff matrix of the game. The changing frequencies of the different strategies are modelled using the *replicator equation* (Taylor and Jonker, 1978).

$$\dot{x}_i = x_i(f_i(\mathbf{x}) - \bar{f}(\mathbf{x})) \quad (1)$$

Where  $x_i$  is the frequency of the  $i$ -th strategy,  $f_i$  is the fitness of that strategy given a population state vector  $\mathbf{x} = (x_1, \dots, x_n)$  and  $\bar{f} = \sum_{i=1}^n x_i f_i(x)$  is the mean fitness of the population given that state. The stable equilibria of the population state under the replicator equation determine *evolutionarily stable states* (ESS) to which the population will return if the frequencies are subject to small perturbations.

Here we focus on social interactions with two social strategy types — co-operators and defectors. Although they are the simplest types of game, these two strategy games include the canonical social dilemmas such as the Prisoner's Dilemma. An arbitrary such game can be defined by the  $2 \times 2$  payoff matrix  $G = \begin{pmatrix} R & S \\ T & P \end{pmatrix}$ .  $R$  is the reward for mutual cooperation,  $P$  the punishment for mutual defection,  $T$  the temptation to defect and  $S$  the suckers payoff. The two strategies are labelled  $C$  for co-operate and  $D$  for defect. We impose the condition that  $R > P$  as the benefits of mutual cooperation are assumed to outweigh those from mutual defection. The complete four-dimensional space of games is determined  $R, S, T$  and  $P$ ; varying their relative magnitudes leads to a diverse range of social scenarios. By normalising  $R$  to 1 and  $P$  to 0 it is possible to project this space onto to a two dimensional plane parameterised by  $S$  and  $T$  (Santos et al., 2006) that we call the  $ST$ -plane. This projection is done via the transformation:

$$\begin{pmatrix} R & S \\ T & P \end{pmatrix} \rightarrow \begin{pmatrix} \frac{R-P}{R-P} & \frac{S-P}{R-P} \\ \frac{T-P}{R-P} & \frac{P-P}{R-P} \end{pmatrix} = \begin{pmatrix} 1 & S' \\ T' & 0 \end{pmatrix} \quad (2)$$

This transformation has the important property that every game with  $R > P$  is equivalent to a game on the  $ST$ -plane — there is a corresponding game that has the same dynamics (though the speed of selection may change). This is because the transformation multiplies the replicator equation

by a constant, leaving the evolutionary stable states determined by the equation's fixed points unchanged. The projection is valid whenever  $R \neq P$  (which is always true for the games we are interested in as  $R > P$ ). This makes the  $ST$ -plane an extremely useful tool to aid conceptual understanding as a representative subset of the two-strategy social dilemmas. The convention is to assume that mutual cooperation is preferable to unilateral cooperation ( $R = 1 > S$ ) and to an equal probability of unilateral cooperation or defection ( $2R = 2 > T + S$ ) (Macy and Flache, 2002), hence the  $ST$ -plane is plotted for the region  $-1 \leq S \leq 1$ ,  $0 \leq T \leq 2$ . Note that we assign a neutral payoff  $P = 0$  to mutual defection; recent work has suggested that ecological constraints leading to negative payoffs for one or both of  $R$  and  $P$  may lead to alternate pathways to altruism in the absence of population structure (Doncaster et al., 2013).

Social dilemmas essentially occur when there is a conflict between the rational outcome and the Pareto-efficient outcome, the individually rational choices for each player leading to a deficient outcome for both. This can arise due to *greed*, the difference between unilateral defection and mutual cooperation ( $T - R$ ), or *fear*, the difference between unilateral cooperation and mutual defection ( $S - P$ ), or both (Santos et al., 2006). These two factors correspond to the two axes of the  $ST$ -plane. The lines  $S - P = 0$  and  $T - R = 0$  split the  $ST$ -plane into four quadrants corresponding to four fundamental two player games that cover the most common types of conflict (Figure 1):

The *Harmony game* ( $R > T > S > P$ ), the least seen of the four as there is no social dilemma — group and individual interests are aligned with cooperation always the most successful strategy. A population of all cooperators is the ESS.

The *Prisoner's Dilemma* ( $T > R > P > S$ ) where the ESS is a population of no cooperators. The Prisoner's Dilemma is a particularly important example of a game and it models scenarios in which individual selection results in defection, to the detriment of the population as a whole.

The *Snowdrift game* ( $T > R > S > P$ ), an anti-coordination game in which interactions with other strategies carry higher payoffs than same-strategy interactions. The Snowdrift game is thus significant as the only game that sustains a stable polymorphic population — the evolutionarily stable state has  $\frac{S-P}{S+T-R-P}$  cooperators.

The *Stag-Hunt game* ( $R > T > P > S$ ), a coordination game in which populations of all cooperators and no cooperators are both ESS. There is an unstable equilibrium with  $\frac{S-P}{S+T-R-P}$  of the population cooperators which divides the two basins of attraction; this is the only game in which the initial frequency of cooperators is significant in determining the ESS.

Figure 1: The  $ST$ -plane showing the four fundamental games and how they are determined by the regions in which the different ESS exist.

## Model Details

To investigate the effects of population-structuring trait assortment on the evolution of population structures favourable to cooperation we created an evolutionary algorithm based on a fixed size population of asexual agents living in non-overlapping generations. A range of potential assorting behaviours are abstractly represented by having agents physically cluster to varying extents determined by their population-structuring traits. This physical assortment influences fitness by affecting who each agent plays with, specifically as each agent's fitness is determined by playing a specified evolutionary game  $G$  against its nearest neighbour.

The model consists of a population of  $P = 100$  agents living in a continuous space that is topologically toroidal. Each agent is represented as a circle  $r = 4$  units in radius. The dimensions of the world is  $100r \times 100r$  units. Each agent's genotype is haploid with two *loci* — a social trait gene that determines its social behaviour (with either 'co-operator'  $C$  or 'defector'  $D$  alleles) and a population-structuring trait with alleles  $A$  for assorting behaviours and  $M$  for freely mixing behaviour. This gives four genotypes:  $CA$ ,  $DA$ ,  $CM$  and  $DM$ . The model is initially populated with these four genotypes present at equal frequency with agents placed randomly in the world.

There are two stages to the evolutionary algorithm. First the agents selectively aggregate for  $T = 10000$  timesteps. Then each member of the population plays a game with its nearest neighbour to determine its fitness. 'Nearest neighbour' is not a symmetric relationship, so while all agents play at least one game (against their own nearest neighbour), some may be played against multiple other times by other agents that have it as their nearest neighbour. As all the games here are symmetric this is equivalent to the agent playing multiple times with different opponents. For this model, an agent's fitness was defined to be its average payoff received per interaction rather than cumulative payoff;

we chose not to reward or penalise an agent for being involved in multiple games. Recording the payoff of the focal player would have also achieved this result but would mean a co-operator closest to another co-operator but surrounded by defectors received the same payoff as a co-operator with no defectors near it; however, there are arguments in favour of other mechanisms and the choice of average payoff represented a trade-off. After the fitnesses were calculated the population was reproduced using tournament selection up to the fixed size  $P$  again: for  $P$  repetitions two agents were drawn from the population and the agent with the highest fitness (or a random agent if they had equal fitness) is reproduced clonally with a small chance of mutation. To represent the intuition that population structure evolves more slowly than social behaviours, the mutation rate for the social behaviour allele was set to a probability  $m_{SB} = 0.01$ , while the probability of a mutation of the population-structuring trait was  $m_{PST} = m_{SB}/2$ .

The agents' movement is modelled by a variation on gravitational attraction. To simplify calculations, each agent is defined to have a mass of 1. The 'gravitational' force between agents  $i$  and  $j$  is then calculated as  $\frac{G_{i,j}}{d^2}$ . Here  $d$  is the distance between the two agents' centers taking into account the fact that the world is toroidal.  $G_{i,j}$  is the attractive constant between the two agents, which is determined by their genotypes and three parameters -  $\alpha$ ,  $\beta$  and  $\gamma$ . These parameters influence the levels of first and second-order assortment in the model:

- $\alpha$  is the attractive force that agents with the assorting allele  $A$  feel towards agents with the same social trait as themselves. So agents with the genotype  $CA$  feel an attractive force of strength  $\alpha$  towards other  $CA$  and  $CM$ -typed agents.
- $\beta$  is the attractive force between agents with the assorting PST allele  $A$ .
- $\gamma$  is the attractive force between agents with the mixing PST allele  $M$ .

Figure 2 shows diagrammatically the different forces that exist between each genotype. The combined forces can be tabulated to give the strength of attraction between genotypes (Table 1). Note that the attractive forces are not symmetrical, unlike real models of gravitation — agent  $i$  may be attracted to agent  $j$  more than  $j$  is to  $i$ .  $G_{i,j}$  is then computed as  $rg$  where  $g$  is the attractive force from agent  $i$  to agent  $j$  as given in the table.

There is also a repulsive force with magnitude -1 that effects the agents when they are closer than  $2r$  apart that prevents the agents from overlapping. At each timestep the forces between all agents are calculated and the net force  $F_i$  for each agent calculated. Friction is then accounted for using the equation  $F_i = F_i - 0.2v_i$  where  $v_i$  is the agent's

Figure 2: The attraction between the different genotypes is determined by the three parameters  $\alpha$ ,  $\beta$  and  $\gamma$

	CA	DA	CM	DM
CA	$\alpha + \beta$	$\beta$	$\alpha$	0
DA	$\beta$	$\alpha$	0	$\alpha$
CM	0	0	$\gamma$	$\gamma$
DM	0	0	$\gamma$	$\gamma$

Table 1: The attractive force from an agent of one genotype (rows) to an agent of another genotype (columns).

previous velocity. Each agent's acceleration, velocity and position are then calculated and updated using numerical integration and the standard equations of motion in a plane using an integration timestep of 0.1.

## Model Scenarios

The model was run using four different sets of parameters, the relative strengths of  $\alpha$ ,  $\beta$  and  $\gamma$  defining four different scenarios with respect to the levels of first and second-order assortment and the nature of the second-order assortment:

**No Assortment** ( $\alpha = 0$ ,  $\beta = 0$ ,  $\gamma = 0$ ). In this control scenario there is no attraction between agents. Consequently each agent's nearest neighbour is randomly determined by the initial placement of agents in the world and frequencies of the social strategies are expected to reach the equilibrium of the game being played.

**First-Order Assortment Only** ( $\alpha = 1$ ,  $\beta = 0$ ,  $\gamma = 0$ ). In this scenario, the only assortment is between social behaviours, where agents with the assorting population-structuring trait are attracted to agents with the same social strategy traits, regardless of whether or not the other agent possesses the assorting trait.

**Emergent Second-Order Assortment** ( $\alpha = 1$ ,  $\beta = 1$ ,  $\gamma = 0$ ). In this model agents with the assorting trait are attracted to others with the same strategy, but there is also attraction between agents with the assorting trait and other agents with the assorting trait. This produces a scenario in

which second-order assortment is tied to the mechanism that generates first-order assortment, as may be the case where strategy-assorters possess greenbeard traits.

**Enforced Second-Order Assortment** ( $\alpha = 1, \beta = 1, \gamma = 1$ ). In this model as well as first order assortment there is also uniform assortment on population-structuring traits. This is intended to produce a situation in which levels of assortment are uniform across different traits such as may be the case with relatedness.

## Results

Clustering occurs in the model as the agents aggregate. In the control scenario, no clustering takes place. In the scenario with only first-order assortment, cooperators cluster with cooperators and defectors with defectors. Predominantly though it is agents with the *CA* genotype grouping with other *CAs* and *DAs* grouping with *DAs* as these are the agents attracted to others with the same strategy allele. In the second variation cooperators and defectors cluster together, with *CAs* and *DAs* at the heart of the clusters and *CMs* and *DMs* at the edges attracted to other cooperators and defectors respectively. In the third scenario where second order assortment is enforced the clusters are more mixed.

To investigate the effects of second-order assortment over a wide range of social dilemmas we took a  $21 \times 21$  lattice of points on the *ST*-plane spaced 0.1 units apart and ran each scenario for every game on the lattice. Each scenario was repeated 5 times for every game and the results averaged. One of the dynamics in the model is that there is no selective difference between individuals with the same social strategy allele in the absence of individuals with the other social strategy allele. The difference in fitness between, for instance, the *CA* and *CM* genotypes comes from their different interactions with the *DA* and *DM* genotypes. So when the model reaches a state in which only one of the social strategy alleles is present then there is no selective pressure between them and their frequencies begin to take a random walk. Experimental testing indicated 20 generations proved a balance between letting the model reach equilibrium and mitigating the effects of the random walk, so this was the length of each run of the model.

Our hypothesis was that increasing second-order assortment would increase the spread of the assorting population-structuring trait. We found some support for this view but with complications, some of which were obvious in retrospect. Figure 3 plots the mean absolute frequency of the *C* allele over the *ST*-plane in all four models. In all scenarios in which there is assortment, cooperators perform better than in the control. However, counter to our initial expectations, cooperation is more successful when there is just assortment on social strategies.

Figure 4 plots the mean frequencies of the *A* allele over

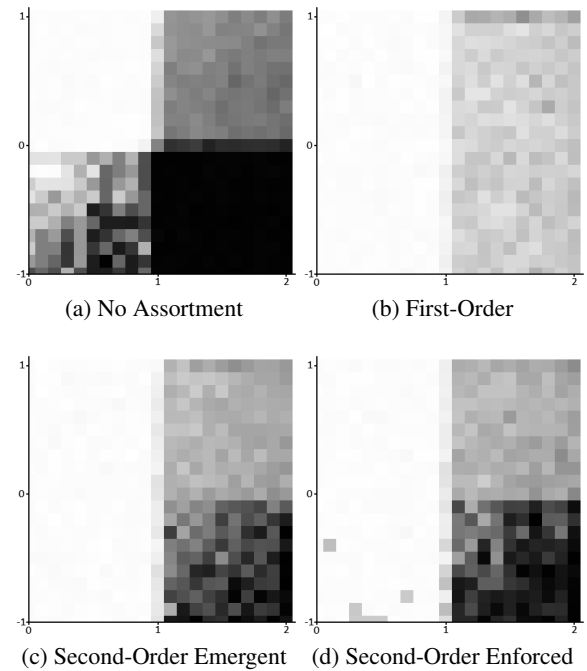

Figure 3: The mean absolute frequency of the *C* allele over the *ST*-plane in all four models on a scale where white indicates 100% cooperators, black 100% defectors.

the *ST*-plane. In the control model there frequency of the *A* is essentially random. In the other models, as expected, increasing levels of assortment increases the spread of the *A* allele. These results are summarised in Table 2 which records the mean frequencies of the *C* and *A* alleles over all games and all runs. As the table shows, there is essentially no net change in frequencies over the whole of the *ST*-plane in the control model. In the three scenarios with assortment, the frequencies of the *C* and *A* alleles increase, but with a trade-off between increased levels of cooperation and assortment on the population-structuring trait.

Scenario	Mn <i>C</i>	Var <i>C</i>	Mn <i>A</i>	Var <i>A</i>
No Assortment	0.505	0.140	0.501	0.005
First-Order	0.814	0.019	0.669	0.017
2 <sup>nd</sup> -order Emergent	0.748	0.088	0.684	0.025
2 <sup>nd</sup> -order Enforced	0.729	0.103	0.731	0.028

## Mathematical Model of Altered Interaction Frequencies using the Replicator Equation

Agent-based simulation models like the one presented here are subject to noise and it can be difficult to tune the desired

Figure 4: The mean frequencies of the  $A$  allele over the  $ST$ -plane on a red-white-blue scale. Red indicates the  $A$  allele decreases in frequency ( $< 0.5$ ), blue that the  $A$  allele increases in frequency ( $> 0.5$ )

behaviours precisely, so there are benefits to reproducing the results in a mathematical model. Here we present a formalism to do so by modifying the replicator equation. The replicator equation models the evolutionary success of a group of genotypes based on the difference between the fitness of the genotype and the mean fitness of the population. The fitness of a genotype is given by its expected payoff based on social dilemma it is engaged in — the payoff for its interaction with each other genotype multiplied by the probability of interacting with that genotype. When the population is freely mixed, these interaction probabilities match the frequencies at which the genotypes occur in the population, but they can be changed by population-structuring mechanisms.

A population state vector  $x \in S_n$  is a vector of the frequencies of different genotypes in a population; alternatively it can be viewed as the probabilities of interacting with a given genotype. The entries of the vector must sum to 1 so it is defined on the simplex  $S_n = \{(x_1, \dots, x_n : \sum_i^n x_i = 1)\}$ . We can define a family of  $n$  *interaction functions*  $e_i : S_n \rightarrow S_n$  that map the population vector to the actual frequencies at which the  $i$ -th genotype encounters other genotypes. The fitness of the type is the composition of the fitness and interaction functions  $f_i \circ e_i(x)$ , and the mean fitness is  $\sum_j^n x_j f_j \circ e_j(x)$ . This gives the new replicator equation:

$$\dot{x}_i = x_i \left( f_i \circ e_i(x) - \sum_j^n x_j f_j \circ e_j(x) \right) \quad (3)$$

The key idea here is that essentially whenever the replicator equation is used there an implicit interaction function, but in a well-mixed population the interaction functions are just the identity. This generalises the replicator equation by explicitly recognising other interaction functions. The set of fitness functions  $g_i : g_i = f_i \circ e_i$  then defines a new game that when played in a well-mixed population is equivalent to the original game played with the given population structure. If the interaction functions can be represented by matrices then they can be used to find the payoff matrix for the transformed game, but that does not apply in this instance where the interaction functions are non-linear.

The non-linearity of the interaction functions in practise is often forced by the requirement that they map valid population states to valid population states (where the entries sum to 1). In general any map of  $S_n$  can be normalised to one of  $S_n$  to itself by dividing the resulting vector by the sum of its entries, but this results in non-linearity. As long as the interaction functions are continuous though the replicator equation can still be used.

### Modelling the Results with Interaction Functions

We used the formalism of interaction functions to mathematically model the results of the simulated scenarios. This was done by constructing interaction functions based on data from the simulations. First we define the four strategy game in the absence of interaction functions. If we consider the strategies to be  $x_1 = CA$ ,  $x_2 = DA$ ,  $x_3 = CM$ ,  $x_4 = DM$  then for an arbitrary social game  $G = \begin{pmatrix} R & S \\ T & P \end{pmatrix}$  the matrix of the full four strategy game is:

$$\begin{pmatrix} R & S & R & S \\ T & P & T & P \\ R & S & R & S \\ T & P & T & P \end{pmatrix} \quad (4)$$

This is then modified using interaction functions. To represent the changed number of interactions due to the population structure we use a simple non-linear interaction function — multiplying each entry in the population state vector by a scalar representing an increased chance of encountering that genotype and then normalising the resulting vector so the entries sum to 1. The scalars were calculated by running the model until the first reproduction event (at  $T = 10000$ ) 100 times starting from evenly distributed population frequencies and recording the total number of games played between each pair of genotypes. Dividing this by the total number of interactions gave the mean frequencies at which a given genotype would encounter each other genotype when the actual frequency of each genotype was 0.25, so dividing

again by 0.25 gives the the actual encounter rate between different genotypes as a multiple of what would have been expected in a well-mixed population. We used these scalars to define the interaction functions for the four types in the model. This was a basic way of determining the interaction functions — a more complex way would have been to generate scalars for different actual population frequencies and interpolate between them to create more complex interaction functions. However, this simple method was sufficient to capture the behaviour of the three non-control models; the match between the results is illustrated in Figure 5.

	CA	DA	CM	DM
CA	2.32	0.14	1.19	0.36
DA	0.13	2.35	0.33	1.18
CM	1.54	0.44	0.93	1.09
DM	0.46	1.53	1.09	0.92
CA	2.14	0.93	0.72	0.20
DA	0.93	2.15	0.21	0.70
CM	0.96	0.28	1.22	1.54
DM	0.26	0.94	1.55	1.25
CA	2.22	1.07	0.49	0.22
DA	1.06	2.21	0.22	0.50
CM	0.51	0.23	1.50	1.76
DM	0.24	0.54	1.77	1.45

Table 3: The rows define the interaction functions giving the coefficients that modifying how likely it is for the row genotype to encounter the column genotype for the three scenarios with assortment, listed in order.

Table 3 gives the interaction coefficients that were used to define the interaction functions for the three scenarios in which there was assortment in the model. For example the first row defines the interaction function  $e_1$ , describing the transformation in the interaction frequencies for the genotype  $CA$  in the social strategy assortment-only model:

$$e_1 \begin{pmatrix} x_{CA} \\ x_{DA} \\ x_{CM} \\ x_{DM} \end{pmatrix} = \frac{1}{2.32x_{CA} + 0.14x_{DA} + 1.19x_{CM} + 0.36x_{DM}} \begin{pmatrix} 2.32x_{CA} \\ 0.14x_{DA} \\ 1.19x_{CM} \\ 0.36x_{DM} \end{pmatrix}$$

## Discussion

Our expectations for this model were that increasing levels of assortment on population-structuring traits (PSTs) would lead to the increased prevalence of the PST that supported cooperative behaviours — in this model represented by a PST that directly increased correlated interactions between individuals with the same social strategy. This was true, but we did not anticipate that there would be a degree of trade-off between increased levels of the cooperative ( $C$ ) and assorting ( $A$ ) alleles. The comparison of the different scenarios reveals that cooperative strategies are more successful

when there is just first order assortment, though the frequency of cooperators still increases when there is second-order assortment relative to when there is no assortment at all.

Figure 5: Visual comparison of simulation model (SM) results and the mathematical model (MM) using interaction functions for the three scenarios with assortment. The simulation model results are as in Figures 3 and 4, the mathematical model graphs reproduce these scenarios.

The reason for this trade off is that assortment on social strategy and population structuring traits are not orthogonal processes. When there is just social strategy assortment, cooperators interact preferentially with cooperators and defectors with defectors, greatly reducing the number of cross-strategy interactions. The inclusion of assortment on the population structure alleles reduces this effect by bringing together cooperators and defectors with the same PST allele. While increasing second order assortment decreases the frequencies of co-operators (relative to strategy assortment only), it increases the spread of the PSTs that ultimately promote cooperation. Hence essentially second order assortment decreases the dependency between cooperation and cooperation-promoting PSTs; when there is second-order assortment the  $A$  allele is able to spread even when the local social game is a prisoner's dilemma dominated by defectors.

An alternate way of looking at this is that it demonstrates that the dominant social behavioural trait does not necessarily have to control the evolution of population structure. This is an important result for social niche construction – population structures that support enhanced cooperation must be able to evolve even in conditions unfavourable to coop-

erative behaviours or social niche construction would be a mechanism that just accelerates the evolution of cooperation rather than enabling it where otherwise defection would be favoured. If we imagine that there is a separation of timescales where population structures evolve more slowly than social behaviours then when there is second-order assortment on PSTs, population structures can evolve to become more supportive to cooperation even when the current social dilemmas are dominated by defectors. This would then establish a basis in population structure for cooperative traits to then spread more easily when conditions change to become more favourable.

The model could be extended in a number of ways, such as by allowing for repeated interactions and hence iterated strategies, or examining a wider range of model parameters. The successful realisation of the simulation results in a mathematical model using interaction functions to change the replicator equation also opens up avenues for future work. In particular it is possible to more precisely model different levels of first and second-order assortment using interaction functions; because the assortment in the simulation model is generated by the gravitational attraction it is difficult to tune and potentially presents an issue in comparing the results across different scenarios. Interaction functions have many potential applications that can be pursued beyond this model; they can provide a general mechanism to determine the effective game played when types interact within a population at non-random frequencies and hence allow comparisons between the actual and effective games that are being played by the population in a principled manner. This work also demonstrates that they can be applied to empirical or simulation-derived data to model the results mathematically.

In conclusion, here we have shown that although second-order assortment on population structuring traits can partially disrupt assortment on social behaviours, it increases the range of behaviours in which population structures that support increased cooperation can evolve.

## Abstract

Gene regulatory networks (GRNs) comprise the interacting genes and gene products that drive genetic regulation within the cell. Because of the vital role they play in producing cell function, GRNs are robust to a variety of perturbations, including genetic mutation. There are multiple underlying causes for this robustness, including topological properties of GRNs, such as their degree distribution. Another topological property, assortativity, has recently been attributed to the robustness of GRNs. Assortative GRNs were found to have smaller in-components (ICs) than their disassortative counterparts, and this led to increased robustness to multiple types of genetic mutation. However, some assortative GRNs lacked the distinctive small ICs, yet were still robust. This suggests that assortativity affects robustness via multiple mechanisms, and unraveling these is a necessary step for understanding which specific features of GRNs give rise to their robustness. Here, we uncover a separate route by which assortativity affects robustness, whereby assortativity influences the characteristic path length of the GRN, which in turn alters robustness.

## Introduction

Gene expression produces the complex machinery necessary for cellular life, and its regulation is a crucial means by which cells can assume specific functions. For example, the regulation of gene expression enables cells to respond to different environments (Gasch et al., 2000; Causton et al., 2001) and navigate diverse paths of differentiation to produce distinct cell fates (Davidson, 2006; Huang et al., 2005).

One of the cell's implicit constructs that accomplishes this regulation is its network of gene-gene interactions, in which the product of one gene directly influences the expression of another gene, as happens with transcription factors. This network is referred to as a gene regulatory network (GRN). Because GRNs are often involved in critical biological functions, it is important that they are robust to genetic perturbation, such as gene knock-out (Jeong et al., 2001) or the rewiring of regulatory interactions (Isalan et al., 2008).

Several theoretical studies have attempted to elucidate the source of this robustness, and one source appears to be GRN topology. For example, GRNs that possess heavy-tailed degree distributions were shown to be more robust than those

that have other degree distributions (Aldana and Cluzel, 2003). This observation has been supported by empirical findings that suggest real-world GRNs have heavy-tailed degree distributions (Babu et al., 2004).

Assortativity is another topological property that has been shown to vary in real-world networks (Newman, 2002; Foster et al., 2010). The assortativity of a GRN measures the tendency for genes to interact with other similar genes. One measure of assortativity considers whether pairs of interacting genes have similar numbers of connections in the GRN, and this is referred to as degree assortativity. Recently, we presented theoretical work which showed that the increased degree assortativity of a GRN produces increased robustness to a variety of genetic perturbations, including point mutations (Pechenick et al., 2012) and gene birth (Pechenick et al., 2013). This occurs via a reduction in the average size of the in-components (ICs) of a GRN. An IC of a gene is the set of all other genes in the GRN which can directly or indirectly influence that gene's expression. We observed that IC sizes shrink with increasing assortativity, and showed how this explains the increased robustness (Pechenick et al., 2012). However, this mechanism did not explain all the observed changes to robustness, as some GRNs displayed increased robustness with increased assortativity but did not exhibit corresponding changes to their IC sizes. This observation invites further inquiry: What is the alternative route by which increased assortativity leads to increased robustness?

In this study, we uncover an additional mechanism whereby assortativity influences the robustness of GRNs. We first show that IC sizes do not always shrink with increasing assortativity, and that the GRNs with unaffected ICs are still more robust than their less assortative counterparts. We then show that while ICs are unchanged in these GRNs, their characteristic path length increases with increasing assortativity. Finally, we demonstrate that characteristic path length generally affects the robustness of GRNs.

Figure 1: A small Boolean network example. (A) This network is composed of 3 nodes and 4 directed edges. Each node possesses a look-up table with the *cis*-regulatory logic that determines the dynamics of the Boolean network. This logic defines the expression state of the node at time  $t + 1$  as a function of the states of its inputs at time  $t$ . For example, the logic for node  $a$  shows how each possible combination of expression states  $\sigma_b(t)$  and  $\sigma_c(t)$  of the inputs at time  $t$  dictate the expression state  $\sigma_a(t + 1)$ . (A; box) The *cis*-regulatory logic for the entire network is its genotype. (B) Starting with the initial configuration  $\Sigma_0$  at time  $t = 0$ , the states are updated according to the genotype until they repeat, forming an attractor that is analogous to a phenotype. Here, the attractor length is two. (C) The in-component (IC) of node  $a$  is the set  $\{a, b, c\}$  (light grey), which includes  $a$  and all other nodes that directly or indirectly provide input to  $a$ . The ICs for  $b$  and  $c$  are both  $\{b, c\}$  (dark grey).

## Methods

### The Model

Random Boolean networks were used to computationally model genetic regulation (Kauffman, 1969), and will herein be referred to as gene regulatory networks (GRNs). In these GRNs, nodes represent genes and edges represent directed regulatory interactions between genes where the regulator regulates the target gene (Figure 1A). Binary gene expression is represented by the Boolean state of each gene, which is dictated at discrete time points by the Boolean functions that define the possible outcomes of the regulatory interactions. Boolean functions represent the *cis*-regulatory logic for each gene, and are commonly encoded as truth tables (Figure 1A). The state of a gene  $\sigma_i(t + 1)$  is determined by

a Boolean function  $f$  which considers the states of the  $k_{in}$  regulators of node  $i$  at time  $t$ :

$$\sigma_i(t + 1) = f_i(\sigma_{i_1}(t), \dots, \sigma_{i_{k_{in,i}}}(t)), \quad (1)$$

where  $\sigma_{i_1}, \dots, \sigma_{i_{k_{in,i}}}$  are the states of the  $k_{in,i}$  regulators of node  $i$ . This function is deterministic, and thus the states of all the genes that exist at the initial time point 0, referred to as configuration  $\Sigma_0$ , will invariably produce the subsequent configuration  $\Sigma_1$  at the next time point. In combination with the finite number of possible configurations ( $2^N$ , where  $N$  is the number of genes in the GRN), this determinism guarantees that once a configuration is encountered, a sequence of configurations will repeat indefinitely:

$$\Sigma_0 \rightarrow \dots \rightarrow \Sigma_t \rightarrow \dots \rightarrow \Sigma_{t+l-1} \rightarrow \Sigma_t \rightarrow \dots, \quad (2)$$

where  $l$  is the number of configurations in the repeated sequence, called an attractor of length  $l$  (Figure 1B). This represents a stable gene expression pattern for the GRN (Huang et al., 2005). Although general and abstract, these models have successfully recapitulated cellular responses in the yeast *Saccharomyces cerevisiae* (Serra et al., 2004), the fly *Drosophila melanogaster* (Albert and Othmer, 2003), the plant *Arabidopsis thaliana* (Espinosa-Soto et al., 2004), and the sea urchin *Strongylocentrotus purpuratus* (Peter et al., 2012).

### Genotype-to-Phenotype Mapping

In order to study how these GRNs maintain their function in the face of genetic perturbation, it is first necessary to explicitly define their mapping of genotype-to-phenotype. The *cis*-regulatory logic of the entire GRN was considered its genotype (Pechenick et al., 2012; Payne et al., 2013) (Figure 1A; box), as it dictates the overall dynamics of the GRN. The attractor that results from this genotype and some initial configuration  $\Sigma_0$  represents a phenotype of the GRN (Figure 1B) (Huang et al., 2005).

### Robustness

Upon establishing the genotype-to-phenotype mapping of these GRNs, the robustness of a phenotype to genetic perturbation must be defined in terms of a specific perturbation (Wagner, 2005). We considered point mutations to the genotype of the GRN, which represent mutations to the *cis*-regulatory regions of the genes in the GRN (Pechenick et al., 2012; Payne et al., 2013). The functional impact of such mutations has been demonstrated in a number of biological contexts (Wray, 2007), such as the patterning of bristles on the fly larvae *Drosophila sechellia* (Sucena and Stern, 2000), the skeletal development of the fish *Gasterosteus aculeatus* (Shapiro et al., 2004), and the branching structure of maize *Zea mays* (Clark et al., 2006).

To estimate robustness, a random walk was conducted in the genotype space of a GRN to determine the robust-

ness of the corresponding phenotype to genotypic perturbation. First, an initial configuration  $\Sigma_0$  and *cis*-regulatory logic were randomly selected for the GRN. This conservative approach eliminates any assumptions about the initial conditions of biological GRNs. Then, the genotype was subjected to a single bit flip. The attractor that resulted from  $\Sigma_0$  and the mutated *cis*-regulatory logic was then compared to the original attractor, and if they matched the mutation was considered neutral and the new *cis*-regulatory logic was preserved as the starting point for the next step in the random walk. Otherwise, the new *cis*-regulatory logic was discarded, and the next step was attempted using the *cis*-regulatory logic from the previous step. Upon completing the random walk, the proportion of mutations that were neutral was used as an estimate of robustness. This estimate approximates the average genotypic robustness for all genotypes that comprise a single phenotype, which is the definition of phenotypic robustness proposed by Wagner (2008).

### Construction of GRNs

GRNs with a heavy-tailed output degree distribution were constructed as follows: For each gene  $i$  in a GRN with  $N$  genes, its number of regulatory targets  $k_{\text{out},i}$  was selected from a power-law distribution (Darabos et al., 2009):

$$p(k_{\text{out}}) = \frac{1}{Z(\gamma)} k_{\text{out}}^{-\gamma}, \quad (3)$$

where  $Z(\gamma) = \sum_{j=1}^N j^{-\gamma}$  is the normalization constant. This generated an out-degree sequence  $k_{\text{out},1} \dots k_{\text{out},N}$ , which was used to randomly select the  $k_{\text{out},i}$  regulatory targets for each gene  $i$ . The resulting in-degree sequence  $k_{\text{in},1} \dots k_{\text{in},N}$  approximated a Poisson input degree distribution. The combination of Poisson input and power-law output degree distribution closely resembles empirical real-world GRN data, such as those from the microbes *E. Coli*, *B. Subtilis*, and *S. cerevisiae* (Aldana et al., 2007).

### Assortativity

Degree assortativity ( $r$ ), referred to here simply as assortativity, is a global network property that captures the tendency for nodes with similar degrees to share an edge between them. This property was defined by Newman (2002) and is calculated as

$$r = \frac{\frac{1}{M} \sum_i j_i k_i - (\frac{1}{M} \sum_i \frac{1}{2} (j_i + k_i))^2}{\frac{1}{M} \sum_i \frac{1}{2} (j_i^2 + k_i^2) - (\frac{1}{M} \sum_i \frac{1}{2} (j_i + k_i))^2}, \quad (4)$$

where  $M$  is the number of edges in the network,  $j_i$  and  $k_i$  are the degrees of the nodes at either end of edge  $i$ , and  $r$  resides in the domain  $[-1, 1]$ ;  $-1$  indicates maximum dissimilarity and  $1$  indicates maximum similarity between degrees of nodes that share an edge. In a directed network,  $j_i$  and  $k_i$  may each be one of two types of degree, in- and out-degree, which results in four possible types of assortativity (Foster et al., 2010). For the purposes of this study, only out-degree was considered, as in Pechenick et al. (2012, 2013).

### In-Components (ICs) and Characteristic Path Length

An in-component (IC) is a local network property. The IC of a node  $a$  corresponds to the set of nodes that are capable of influencing  $a$  (Figure 1C). The mean size of the ICs of all nodes in a network provides a measure of the extent to which nodes can affect other nodes in that network, and is calculated as

$$\bar{S} = \frac{\sum_{i=1}^N S_i}{N}, \quad (5)$$

where  $S_i$  is the IC size of node  $i$ , and  $N$  is the number of nodes in the network.

The characteristic path length is a global network property that also captures the relative ease with which information can flow between nodes in a network (Watts and Strogatz, 1998). This property is calculated by determining the shortest directed path between all pairs of nodes, and taking the mean of all existing paths. If a path does not exist between a pair of nodes, that pair is not considered in the calculation.

### GRN Rewiring

Upon construction, a GRN with  $N$  genes has an out-degree sequence  $k_{\text{out},1} \dots k_{\text{out},N}$  and an in-degree sequence  $k_{\text{in},1} \dots k_{\text{in},N}$ , and together these are referred to simply as its degree sequence. It is important to point out that different degree sequences can be drawn from the same degree distribution (Equation 3). In order to examine the effects of various topological properties on GRNs, it was desirable to vary those properties without altering the degree sequence of the GRN. An edge-swap algorithm was thus used to modify topology while keeping both the in- and out-degree of every gene intact (Milo et al., 2003). In each iteration of this algorithm, two edges  $i \rightarrow j$  and  $x \rightarrow y$  were selected, and the regulatory targets were swapped between the regulators to yield two new edges  $i \rightarrow y$  and  $x \rightarrow j$ . If the new edges caused the GRN to be closer to a desired value for a particular topological property, or if no change was observed with respect to this property, then the new edges were kept. Otherwise, the new edges were discarded and the old edges were kept.

### Simulation Design

To examine the relationship between assortativity, mean IC size, and characteristic path length, 2000 weakly connected GRNs with  $N = 30$  and  $\bar{k}_{\text{out}} = 4$  ( $\gamma = 1.55$ ) were constructed. Self-loops were excluded because they trivially increase assortativity without changing mean IC size or characteristic path length, and such exclusion did not affect past results (Pechenick et al., 2013). GRNs with  $\bar{k}_{\text{out}} = 4$  are in the chaotic dynamical regime, which was chosen because these GRNs tend to have large ICs and exhibit dramatic variation in robustness, whereas ordered and critical GRNs exhibit limited changes in robustness as assortativity varies (Pechenick et al., 2012, 2013). The 2000 degree sequences

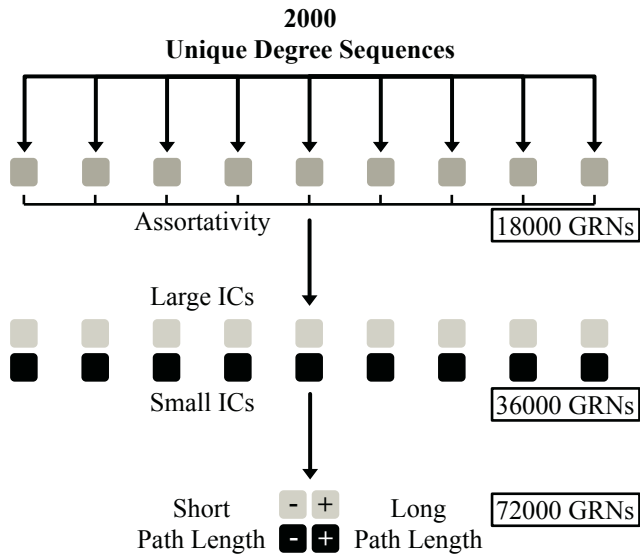

Figure 2: Simulation design flowchart. Beginning with 2000 unique degree sequences, every degree sequence was rewired (preserving degree sequence) to construct GRNs at each of 9 evenly spaced assortativity values. Each GRN was then rewired (preserving degree sequence and assortativity) to produce two new GRNs, one with small and one with large mean IC size. Next, each of those GRNs was rewired (preserving degree sequence, assortativity, and mean IC size), producing one GRN with short and one with long characteristic path length. This final step is only displayed once for clarity.

were then rewired to 9 evenly spaced assortativity values in the range  $[-0.64, -0.02] \pm 0.01$  (Figure 2), where the edge-swap algorithm proceeded until assortativity was within 0.01 of the desired value, as in Pechenick et al. (2013). This resulted in 18000 GRNs, where every degree sequence was represented at every assortativity value. Note that heavy-tailed degree distributions are inherently negatively assortative (Johnson et al., 2010), and the domain of the assortativity values considered here was entirely negative.

To isolate the effects of mean IC size, GRNs were rewired to low and high values for mean IC size. The edge-swap algorithm was allowed to minimize or maximize mean IC size for each GRN until no desired change in mean IC size had been observed for 10000 iterations, and assortativity was constrained within  $\pm 0.02$  of the original 9 evenly spaced values. Here, every degree sequence was represented twice at every assortativity value. We refer to these two classes of GRNs as “small ICs” and “large ICs.”

Then, to isolate the effects of characteristic path length for each of the two classes of GRNs, GRNs were rewired to low and high values for characteristic path length. As before, the edge-swap algorithm was allowed to proceed until the

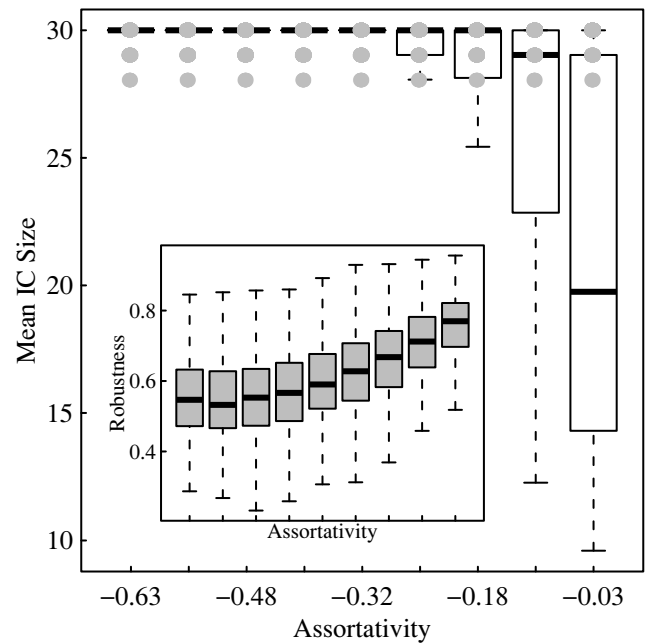

Figure 3: Mean in-component (IC) size vs. assortativity. The mean IC size of the 18000 GRNs decreases as assortativity increases ( $p = 0.025$ , Spearman’s rank correlation on median values). However, 422 (21%) of the 2000 degree sequences do not exhibit a decrease in mean IC size (grey circles). (Inset) Robustness vs. assortativity. Robustness for the 422 degree sequences (3798 GRNs) increases as assortativity increases ( $p \ll 0.001$ , Spearman’s rank correlation on median values). Outliers are omitted from plots for clarity.

desired decrease or increase was not observed for 10000 iterations. Assortativity was constrained within  $\pm 0.02$ , as before, and mean IC size was not allowed to vary at all from its starting value. Here, every degree sequence was represented four times at every assortativity value for every combination of low and high mean IC size and characteristic path length. For more on rewiring networks to obtain multiple desired topological properties, see Holme and Zhao (2007).

The robustness of a GRN was estimated by taking the average of the outcomes for 100 random walks with different initial configurations  $\Sigma_0$  and *cis*-regulatory logic, where each random walk consisted of 500 attempted steps. These parameters were selected as a compromise between accuracy and computational efficiency (Pechenick et al., 2012).

## Results

### *Small mean IC size is not solely responsible for increased robustness.*

Consistent with previous observations (Pechenick et al., 2012, 2013), the mean IC sizes of the 18000 GRNs at 9 assortativity values tended to decrease with increasing assortativity (Figure 3). This decrease in mean IC size was impli-

Figure 4: Mean in-component (IC) size, robustness, and attractor length vs. assortativity for GRNs with either small or large ICs. At every assortativity value, (top) GRNs with large ICs have significantly larger mean IC size, (middle) lower robustness, and (bottom) longer attractors than GRNs with small ICs (all  $p \ll 0.001$ , Wilcoxon rank sum test). Outliers are omitted from plots for clarity.

cated in a corresponding increase in robustness (Pechenick et al., 2012); however, some degree sequences produced GRNs with identical mean IC sizes at every assortativity value (Figure 3; grey circles), and these GRNs also showed increased robustness with increased assortativity (Figure 3; inset). Therefore, a topological mechanism distinct from mean IC size is required to explain the observed increase in robustness for these GRNs.

### ***Both small and large mean IC sizes are possible for the same degree sequences.***

One possible explanation for the two types of GRNs observed in Figure 3 is that certain degree sequences are simply incapable of rewiring in such a way that results in smaller ICs. Likewise, some degree sequences may be forced to form smaller ICs as assortativity increases. If this were true, not only would multiple mechanisms be needed to explain the observed increases in robustness, but these mechanisms would act exclusively on certain degree sequences and not others.

In order to test whether this is indeed the case, we rewired each degree sequence at each assortativity value to try to obtain two new GRNs with a small and large mean IC size (preserving assortativity), respectively (Figure 4; top). At the

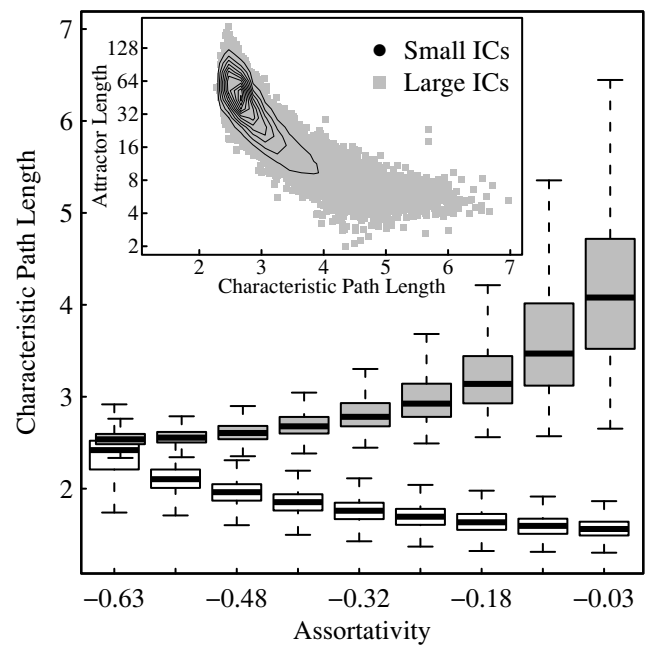

Figure 5: Characteristic path length vs. assortativity. The characteristic path length of GRNs with large ICs increases as assortativity increases, whereas it decreases for GRNs with small ICs (both  $p \ll 0.001$ , Spearman's rank correlation on median values). Outliers are omitted from the plot for clarity. (Inset) Attractor length vs. characteristic path length. The attractor length of GRNs with large ICs decreases as characteristic path length increases, whereas it increases for GRNs with small ICs (both  $p \ll 0.001$ , Spearman's rank correlation on all values). Contour lines are provided as a visual guide for the relative density of points.

lowest assortativity value, where GRNs almost exclusively have large ICs, 47% of degree sequences failed to produce GRNs with smaller ICs. However, this dropped to 13% at the second lowest assortativity value, 2% at the third, and  $< 1\%$  for all other assortativity values. For the top three assortativity values, every degree sequence was able to produce distinct GRNs with either small or large ICs. Therefore, while multiple mechanisms are still necessary to understand how assortativity influences robustness, these respective mechanisms are not restricted to only certain degree sequences. We then estimated robustness for these two classes of GRNs and found that for every assortativity value GRNs with small ICs were significantly more robust than their counterparts with large ICs (Figure 4; middle). This suggests that the previously described mechanism for how small ICs can lead to increased robustness (Pechenick et al., 2012) is generally relevant for GRNs across different degree sequences and at a wide range of assortativity values.

However, since GRNs with large ICs displayed increased robustness with increased assortativity (Figure 4; middle),

Figure 6: For GRNs with large ICs: Characteristic path length, robustness, and attractor length vs. assortativity for GRNs with either short or long characteristic path length. At every assortativity value, (top) GRNs with long characteristic path length have significantly longer paths, (middle) higher robustness, (bottom) and shorter attractors than GRNs with short characteristic path length (all  $p \ll 0.001$ , Wilcoxon rank sum test). Outliers are omitted from plots for clarity.

another general mechanism besides mean IC size is required to explain the effect assortativity has on robustness. In Pechenick et al. (2012), we proposed that mean IC size affects robustness by altering the attractor lengths of GRNs, and we observed here that attractor length decreases with assortativity for both classes of GRNs (Figure 4; bottom). This is consistent with a negative relationship between robustness and attractor length, and suggests that the alternative mechanism producing highly robust GRNs with large ICs is doing so by reducing attractor length.

#### ***Characteristic path length changes with assortativity.***

For the GRNs with large ICs, mean IC size does not change with assortativity (Figure 4; top), so another topological property must be influencing the attractor lengths of these GRNs. We found that the characteristic path length of GRNs changes with assortativity in a manner that is dependent on which of the two GRN classes is being considered (Figure 5). For GRNs with small ICs, characteristic path length shrinks with increasing assortativity, and appears to be associated with a shrinking mean IC size (Figure 4; top). However, for GRNs with large ICs, characteristic path length

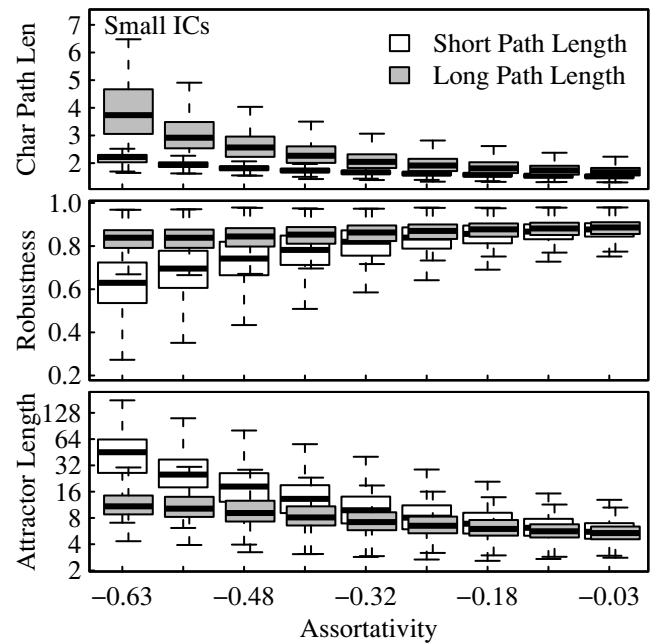

Figure 7: For GRNs with small ICs: Characteristic path length, robustness, and attractor length vs. assortativity for GRNs with either short or long characteristic path length. At every assortativity value, GRNs with long characteristic path length are significantly different from GRNs with short characteristic path length, as in Figure 6 (all  $p \ll 0.001$ , Wilcoxon rank sum test). Outliers are omitted from plots for clarity.

grows with increasing assortativity. These opposing trends are accompanied by two additional opposing trends: For GRNs with small ICs, attractor length is positively correlated with characteristic path length, whereas for GRNs with large ICs, attractor length is negatively correlated with characteristic path length (Figure 5; inset). This is consistent with the decreases in attractor length as assortativity increases for both GRNs with small and large ICs (Figure 4; bottom).

#### ***Long characteristic path length contributes to robustness.***

To determine whether characteristic path length is directly responsible for changes in robustness and attractor length, we varied the characteristic path length of GRNs to their high and low bounds while preserving both assortativity and mean IC size for GRNs with large ICs (Figure 6) and small ICs (Figure 7). For GRNs with large ICs, the maximum characteristic path length that was achievable increased with increasing assortativity (Figure 6; top), which echoes the relationship between these two properties observed in Figure 5. However, these results go on to show that GRNs with longer characteristic path length have higher robustness

(Figure 6; middle) and shorter attractors (Figure 6; bottom) than their counterparts with shorter characteristic path length that possess the same assortativity and mean IC size. These results argue for a direct positive role for characteristic path length in affecting the robustness of GRNs with large ICs at a wide range of assortativity values.

For GRNs with small ICs, although changes in characteristic path length seemed to have the opposite effect on attractor length, and therefore robustness, as GRNs with large ICs (Figure 5; inset), it was unclear whether this represented a direct relationship between the two properties. In particular, for GRNs with small ICs, increasing assortativity produces decreases in both characteristic path length (Figure 5) and mean IC size (Figure 4; top). Since a decrease in mean IC size leads to increased robustness (Figure 4; middle), it is difficult to disentangle the effects of characteristic path length from those caused by changes in mean IC size. By varying characteristic path length independently of both assortativity and mean IC size, we can directly address this.

In contrast to GRNs with large ICs, for GRNs with small ICs, the maximum characteristic path length that was achievable decreased with increasing assortativity (Figure 7; top), likely reflecting a positive association between characteristic path length and mean IC size. However, consistent with the results for GRNs with large ICs, GRNs with small ICs that possess long characteristic path length exhibit higher robustness (Figure 7; middle) and shorter attractors (Figure 7; bottom) than their counterparts with short characteristic path length with the same assortativity and mean IC size. Taken together, these results indicate that although the ability to vary the characteristic path length of a GRN depends on both its mean IC size and its assortativity, adopting a longer characteristic path length leads to higher robustness in a manner that is independent of these other two properties. Therefore, as the assortativity of a GRN increases, one of two things tends to occur that can result in higher robustness. Its mean IC size may shrink, which leads to higher robustness in a manner that dominates the effects of the associated shrinking of characteristic path length. Or, its mean IC size may not shrink, in which case characteristic path length will tend to grow and lead to higher robustness.

## Discussion

We have presented an alternative mechanism by which assortativity influences the robustness of GRNs to mutations in their *cis*-regulatory logic. It is often the case that an increase in assortativity results in a decrease in mean IC size, which increases the robustness of the GRN. However, even when mean IC size does not change, robustness nonetheless increases. We have found that in this case, an increase in assortativity leads to an increase in characteristic path length, which is associated with increased robustness. Furthermore, this effect was not limited to GRNs with large mean IC sizes. The assortativity and mean IC size of a GRN does constrain

its characteristic path length. Nevertheless, we have shown that a GRN with a long characteristic path length is on average more robust than a GRN with similar assortativity and mean IC size, but with a shorter characteristic path length.

These results complement previous theoretical work that showed that the characteristic path length of network models influences their dynamics. In contrast to the inverse relationship between characteristic path length and attractor length that we observed, Serra and Villani (2002) showed that decreasing the characteristic path length of cellular automata (CA) led to simpler dynamics. This result is likely due to their use of the majority update rule, which took advantage of the shorter paths to more easily achieve uniform behavior across the network. In line with what we have shown, Lizier et al. (2011) observed that an increase in the characteristic path length of random Boolean networks led to greater information storage and less information transfer, which are properties that they found associated with the simpler dynamics typically found in the ordered dynamical regime.

As we gather more data about the structure of biological GRNs, the results presented in this work will provide a theoretical basis for searching for specific topological features that are indicative of robustness. Indeed, high assortativity would imply robustness, yet its absence would not discount it. A relatively small mean IC size could suggest robustness at a range of assortativity values, and yet it too is not exclusively necessary. In the absence of a small mean IC size, a long characteristic path length would signal robustness that could rival the robustness of a GRN that did possess a small mean IC size. We have shown that any one or a combination of these properties contributes to highly robust GRNs. Furthermore, this study exclusively considered out-degree assortativity, and further work will be necessary to determine how the other types of degree assortativity are involved (Foster et al., 2010). As we continue to map and examine biological GRNs, it will be informative to catalog their topological properties in an attempt to understand whether they depict common or varied evolutionary strategies of achieving robustness.

### Abstract

Artificial life is largely concerned with systems that exhibit different emergent phenomena; yet, the identification of emergent structures is frequently a difficult challenge. In this paper we introduced a system to identify candidate emergent mesolevel dynamical structures in dynamical networks. This method is based on an extension of a measure introduced for detecting clusters in biological neural networks; its main novelty in comparison to previous application of similar measures is that we used it to consider truly dynamical networks, and not only fluctuations around stable asymptotic states. The identified structures are clusters of elements that behave in a coherent and coordinated way and that loosely interact with the remainder of the system. We have evidence that our approach is able to identify these “emerging things” in some artificial network models and in more complex data coming from catalytic reaction networks and biological gene regulatory systems (*A.thaliana*). We think that this system could suggest interesting new ways in dealing with artificial and biological systems.

### Introduction

Artificial life is largely concerned with systems that exhibit different emergent phenomena, life itself being one of the most intriguing ones. Yet defining emergence is a controversial issue, since it is deeply related to the relationship between the observer and the observed system. We will not enter here this debate, but we rather want to stress an aspect of emergence that is often overlooked, i.e. its intermediate-level characteristics.

Most discussions of emergence, as well as its existing theories and models, take into account a two-level system, and describe the bottom-up features of the phenomenon. For example, take the well-known Benard-Marangoni hexagonal convection pattern (Haken H. 2004) that is generated when the heat flow exceeds a certain threshold: here the microscopic level is that of the water “particles” and the macroscopic one is that of the hexagonal convection cells (in this case, the hierarchy of levels is related to their characteristic dimension). There is indeed a further upper

level, i.e. that of the apparatus where the phenomenon takes place; this uppermost level is necessary, and indeed it determines some major features of the phenomenon, as it can be seen e.g. by replacing the free surface with a metallic plate, thereby changing the pattern from hexagonal cells to cylindrical rolls. However the uppermost level is not affected by what happens at the lower levels and it therefore just provides the fixed boundary conditions that allow the establishment of the emergent patterns.

However, at a close look one finds that most emergent phenomena take place at levels that can be regraded as intermediate between pre-existing levels, that are in turn affected by the appearance of the intermediate emergent pattern. This topic is strictly related to the concept of emergence of hierarchies (Salthe, 1985) (Emmeche et al, 1997). Here we focus on the so-called “sandwiched” emergent phenomena, which appear in several fields such as physics, biology and social science (Lane et al, 2009). The most striking case is likely to be that of the formation of organs and tissues in multicellular organisms. Multicellularity predates the formation of organs, so the microscopic and macroscopic levels, i.e. cells and organism, were already in place when organs appeared. However, once they were formed, both organisms and cells were modified. Other examples of sandwiched emergence include the formation of clouds in physics and that of political factions, within parties, in social science, but there are actually very many. Indeed, once the importance of mesolevel emergence has been appreciated, it becomes difficult to find truly two-level systems in the sense defined above.

While in some cases it may be simple to identify the emergent structures or patterns, this is not always the case. Take for example a network of nodes that lacks any explicit all-encompassing spatial regularity, like e.g. a model of a genetic regulatory network with random connections, or a random chemical reaction network. While in spatially regular systems the appearance of regular patterns (like in the Benard case) or of clusters of nodes may be easy to find, in random systems that is by far more difficult.

In real genetic networks a lot of effort has been devoted to identifying frequently occurring motifs, i.e. small connection patterns that are much more frequent than what might be

expected if the network had been completely random; their high relative frequency can be regarded as a hint to the fact that they might have been selected by evolution due to the usefulness of the functions they perform. Indeed, the search for relevant connection patterns in complex networks is an important research topic. However, these approaches are mainly concerned with features that are directly related to the network topology, while here we want to look for structures and patterns that can be observed while looking at the dynamics of the system.

So, in order to escape from a merely topological view, we consider different subsets of the system, looking for those whose elements appear to be well coordinated among themselves and have a weaker interaction with the rest (Mesolevel Dynamical Structures, or MDS, in the following). For each subset of elements we will measure its so-called cluster index, a measure based on information theory that has been proposed by Tononi and Edelman (Tononi et al. 1998). After a suitable normalization procedure we rank the various subsets in order to identify those that are good candidates for the role of partially independent "organs" (note that they not necessarily exist in any network).

### The approach

For the sake of definiteness, let us consider a system  $U$ , our "universe" that is a network of  $N$  elements that can change their state in discrete time, taking one of a finite number  $l$  of discrete values. The value of element  $i$  at time  $t+1$ ,  $x_i(t+1)$ , will depend in a deterministic way upon the values of a fixed set of input elements at time  $t$ , possibly including the  $i$ -th (self-loops are not prohibited).

We will consider the systems' behaviors after an adequate relaxation time, in order to observe its asymptotic states. Given this quasi-equilibrium hypothesis we can estimate the entropy of each element from a long series of states by taking its frequencies  $f_v$  of observed values as proxies for probabilities, so:

$$H_i = -\sum_{v=1}^m f_v \log f_v \quad [1]$$

where the sum is taken over all the possible values an element can take. Of course, the average entropy of the whole system is the average of  $H_i$  taken over all the elements.

In case of a fixed point attractor  $H_i=0$  for every element since each node takes its value with frequency one. In order to apply entropy-based methods, Edelman and Tononi considered a system subject to gaussian noise around an equilibrium point. However nonlinear systems can carry several different attractors, each attractor revealing a particular way of functioning of the system itself: so the composition of all these asymptotic behaviors should help us in finding the parts of the system able to dynamically support them. Our "long data series" therefore will be composed by several repetitions of a single attractor, followed by repetitions of another one, etc. (ignoring the short transients

between the attractors)<sup>1</sup>, the number of repetitions reflecting the nature of the system we are analyzing. There are several different strategies to estimate these attractors' weights: in case of noisy systems a possibility is that of using the persistence time of the systems in each of them (Villani and Serra, 2013), whereas deterministic systems might be analyzed by weighting attractors with their basins of attraction. Given the nature of the cases of this work in the following we opt here for this second choice.

Now let us look for interesting sets of nodes (clusters, from now on). A good cluster should be composed by nodes (i) that possess high integration among themselves and (ii) that are more loosely coupled to other nodes of the system. The measure we define, called the cluster index, provides a value that can be used to rank various candidate clusters (i.e., emergent intermediate-level sets of coordinated nodes).

### The cluster index

Following Edelman and Tononi (Tononi et al. 1998), we will define the cluster index  $C(S)$  of a set  $S$  of  $k$  elements, as the ratio of a measure of their integration  $I(S)$  to a measure of the mutual information  $M(S;U-S)$  of that cluster with the rest of the system.

The integration is defined as follows: let  $H(S)$  be the entropy (computed as before) of the elements of  $S$ . This means that each state is a vector of  $k$  elements, and that the entropies are computed by counting the frequencies of the  $k$ -dimensional vectors. Then:

$$I(S) = \sum_{j \in S} H(x_j) - H(S) \quad [2]$$

So  $I(S)$  measures the deviation from statistical independence of the  $k$  elements in  $S$ , by subtracting the entropy of the whole subset to the sum of the single-node entropies. The mutual information of  $S$  to the rest of the world  $U-S$  is also defined by:

$$\begin{aligned} M(S;U-S) &\equiv H(S) + H(S|U-S) = \\ &= H(S) + H(U-S) - H(S,U-S) \end{aligned} \quad [3]$$

where, as usual,  $H(A|B)$  is the conditional entropy and  $H(A,B)$  the joint entropy. Finally, the cluster index  $C(S)$  is defined by:

$$C(S) = \frac{I(S)}{M(S;U-S)} \quad [4]$$

The cluster index vanishes if  $I=0$ ,  $M \neq 0$ , and is not defined whenever  $M=0$ . These cases, in which  $S$  is statistically independent from the rest of the system, can nevertheless be diagnosed in advance: the  $0/0$  form does not provide any information, whereas  $I(S)/0$  form - with  $I(S) \neq 0$  - points to statistical independence of  $S$  from the rest of the system, and calls for a separate analysis.

<sup>1</sup> Note that - given the nature of the average computation - the particular order of the data vectors on the series do not alter the analysis; in addition the data series can be composed by states belonging to different attractors

$C(S)$  scales with the size of the subsystem, so a loosely connected subsystem may have a larger index than a more coherent, smaller one: to compare the indices of the various candidate clusters it is therefore necessary to normalize their cluster indexes, for example by comparing them with those of subsystems having same size, but belonging to a non-clustered homogeneous system (a “null system”).

The definition of the “null system” is critical: it could be problem-specific, but we prefer a simple solution which is fairly general: given a series of discrete vectors, we compute the frequency of each symbol and generate a new random series where each symbol has a probability of appearing equal to that of the original series. This random null hypothesis is easy to calculate, related to the original data and parameter-free; moreover it satisfies the requirements set by Tononi of homogeneity and cluster-freeness.

The “null system” therefore provide us with a null hypothesis and allows us to calculate a set of normalization constants, one for each subsystem size. For each subsystem size, we compute average integration  $\langle I_h \rangle$  and mutual information  $\langle M_h \rangle$  (subscript  $h$  stands for “homogeneous”); we can then normalize the cluster index value of any subsystem  $S$  using the appropriate normalization constants dependent on the size of  $S$ :

$$C'(S) = \frac{I(S)}{\langle I_h \rangle} \bigg/ \frac{M(S; U-S)}{\langle M_h \rangle} \quad [5]$$

In order to compute a statistical significance index ( $T_c$  in the following) we apply this normalization to both the cluster indexes in the analyzed system and in the null system:

$$T_c(S) = \frac{C'(S) - \langle C'_h \rangle}{\sigma(C'_h)} \quad [6]$$

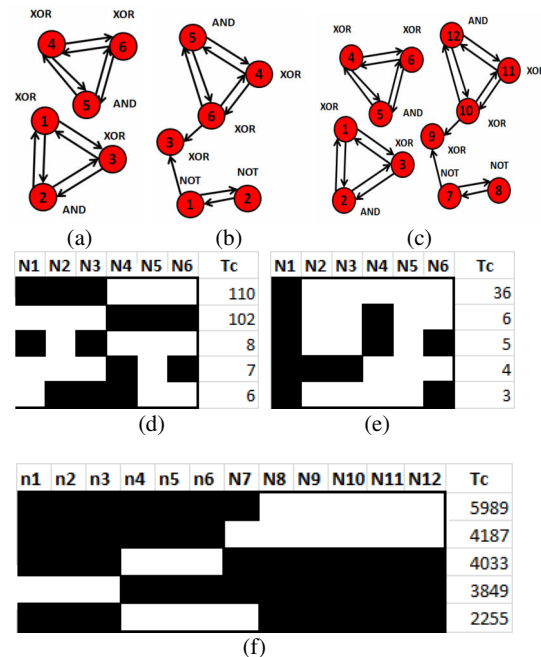

where  $\langle C'_h \rangle$  and  $\sigma(C'_h)$  are respectively the average and the standard deviation of the population of normalized cluster indices with the same size of  $S$  from the null system (Benedettini 2013). Finally we use  $T_c$  to rank the obtained clusters.

## Results

The cluster index has been introduced by Tononi (Tononi et al. 1998) for quasi-static systems; in the previous section we have shown how it could be extended to nonlinear dynamical systems, and in the following we will show the result of the application of this ranking method to some relevant systems, including generic models of gene regulatory networks, models of sets of catalytic chemical reactions and models of specific regulatory networks (*A.thaliana*). The method draws our attention on the subsets of the analyzed system that are highly functionally correlated and that could represent possible candidates MDSs. In the end we will also comment on the fact that our method, although not yet fully developed, outperforms usual correlation techniques.

## Boolean networks

The case study we are going to examine consists of three synchronous deterministic Boolean networks (BNs), described in Fig.1. BNs are an important framework frequently used to model genetic regulatory networks (Kauffman, 1993) (Kauffman, 1995), also applied to relevant biological data (Serra et al. 2004) (Shmulevich et al. 2005) (Villani et al. 2007) and processes (Serra et al. 2010) (Villani et al. 2011). The aim of this case study is to check whether CI analysis is capable of recognizing special topological cases, such as causally (in)dependent subnetworks and oscillators, where the causal relationships are more than binary. Note that given this “more than binary” nature in all the following cases, traditional analyses based on correlation between pairs of variables might fail. For example the computation of Pearson correlation coefficients of the networks of this section does not lead to identify related variables, given that only diagonal elements take non negligible values.

**Figure 1** (a) independent Boolean networks (BN1); (b) interdependent networks (BN2); (c) a system composed by the merging of both the previous networks (BN3). Beside each boolean node there is the boolean function the node is realizing. The second part of the figure shows the matrices illustrating the elements belonging to the clusters (white on figures) and the corresponding  $T_c$  values, for (d) BN1, (e) BN2 and (f) BN3 systems

CI analysis is able to correctly identify the two subnetworks of BN1 (first and second rows). The analysis clusters together 5 of 6 nodes of BN2: those already clustered in BN1, plus nodes 1 and 2 (which negates each other - figure 1b) and the node that compute the XOR of the signal coming from the two just mentioned groups. Indeed, all these nodes are needed in order to correctly reconstruct the BN2 series. The analysis

is able to identify all MDSs also when all the series are merged together (figure 1f, where the top two clusters correspond respectively to the 5 nodes already recognized in BN2 and to the whole BN2 system, while the third and fourth rows correspond to the independent subgraphs of BN1 - see (Villani et al., 2013) for details). Experiments performed using asynchronous update yielded essentially the same results with respect to both CI and correlation analyses.

We would like to point out that CI analysis does not require any knowledge about system topology or dynamics. This information is normally unavailable in real cases; on the other hand, our methodology just needs a data series.

### Perturbing a catalytic reactions system

It is widely believed that the origin of life required the formation of sets of molecules able to collectively self-replicate (Carletti et al., 2008) (Filisetti et al., 2010) (Ganti, 2003) (Luisi et al., 2006) (Mansy et al., 2008) (Rasmussen et al., 2003) (Stano and Luisi, 2010) (Szostak et al., 2001), a phenomenon that may play an important role also in future bio-technological systems (Solè et al., 2007). There are many efforts to identify the dynamical cores of these systems, mainly based on static properties of the reaction networks they are forming (Farmer et al., 1986) (Hordijk et al., 2010) (Kauffman, 1986); in this work we present a first attempt toward a dynamical detection of these systems.

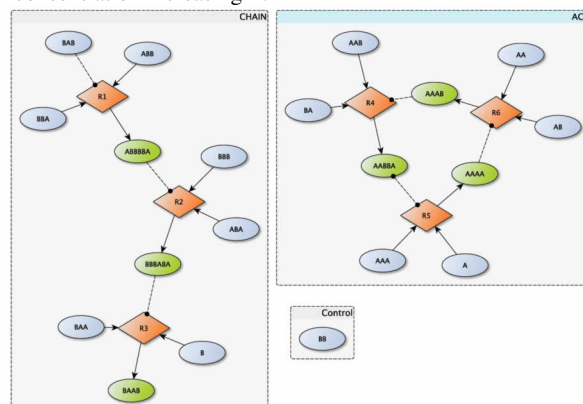

We use a simple system (inspired by a model (Filisetti et al. 2011a) (Filisetti et al. 2011b) (Filisetti et al. 2011c) (Farmer et al., 1986) originally due to Kauffmann (Kauffmann, 1993) (Kauffmann, 1995)) where there are two distinct reaction pathways, a linear reactions chain (CHAIN) and an autocatalytic set of molecular species (ACS) (see figure 2): both reactions pathways occur in an open well-stirred chemostat (CSTR) with a constant influx of feed molecules and a continuous outgoing flux of all the molecular species proportional to their concentration. The dynamics of the system is described adopting a deterministic approach whereby the reaction scheme is translated in a set of Ordinary Differential Equations (ODE) integrated by means a fourth-order Runge-Kutta method (Young and Gregory, 1988).

The main entities of the model are molecular species ("polymers") represented by linear strings of letters A and B, forming together a catalytic reactions system composed of 6 distinct condensation reactions in which two species are glued to create a longer species. The reactions occur only in presence of a specific catalyst, since spontaneous reactions are assumed to occur too slowly to affect the system behavior. Accordingly, in the following the reaction scheme is presented:

According to the three molecular nature of the condensation reaction, reactions occur in 2 two steps: in the former the catalyst binds the first substrate forming a molecular complex, while in latter the molecular complex binds the second substrate releasing the product and the catalyst. The "food set" of the linear chain ( $BAB \rightarrow ABBBA \rightarrow BBBABA \rightarrow BAAB$ ) is formed by the species  $ABB$ ,  $BBA$ ,  $BBB$ ,  $ABA$ ,  $BAA$ ,  $B$ , whereas the food set of and the autocatalytic cycle ( $AABBA \rightarrow AAAA \rightarrow AAAB \rightarrow AABBA$ ) is formed by the species  $BA$ ,  $AAB$ ,  $AAA$ ,  $A$ ,  $AB$ ,  $AA$ . Besides, an independent molecular species  $BB$  not involved in any reactions has been introduced as control species (figure 2).

The asymptotic behavior of this kind of systems is a single fixed point (Vasas et al., 2012), due to the system feedback structure. In order to apply our analysis we need to observe the feedbacks in action, therefore we perturb the concentration of some molecules in order to trigger a response in the concentration of (some) other species. So we temporarily set to zero the concentration of some species (in the example of fig.2 of the species  $ABBBA$ ,  $BBBABA$ ,  $AABBA$ ,  $AAAA$ ,  $AAAB$ ) after the system reached its stationary state<sup>2</sup>: in order to analyze the system response to perturbations we use a 3-level coding, where for each species the digit '0'-'1'-'2' stand respectively for "concentration decreasing", "no change" and "concentration increasing"<sup>3</sup>.

**Figure 2** The chemical system under analysis. Circular nodes depict chemical species, the blue ones stand for those injected on the CSTR (food species) and the green ones represent the more complex species built by specific concatenations of the food species, see reaction scheme in the text. Diamond shapes represent reactions where incoming arrows go from substrates to reactions and outgoing arrows go from reactions to products. Dashed lines indicate the catalytic role of a particular molecular species within the specific reaction context. The kinetic constants of all present reactions have the same value  $k_{dir}=0.0025 \text{ s}^{-1} \text{ mol}^{-1}$ ; the incoming concentration of each food species is 1.0 mol, whereas each second the 2% of the CSTR volume is renewed

<sup>2</sup> In this example the analyzed data series starts from second 200, in order to avoid the initial transient

<sup>3</sup> In such a way we can abstract from the different concentration present on the system, a species being constant if its concentration change from previous time instant is below the threshold of 0.1%

The results clearly indicate the presence of two distinct systems of size 3 (the second and third rows in fig.4a) that correspond to CHAIN and ACS. Note that the leave of CHAIN (BAAB) is not strongly affected by the zeroing of ABBBA species (because the perturbation of this species, root of the linear chain, affects only in a limited manner the following species BBBABA, whose change in turn even lesser affects the concentration of species BAAB...): this attenuation process induces a dynamical hierarchy on CHAIN system, which allows the finer subdivision highlighted by the first row of fig.4a. This phenomenon is absent on ACS, a more homogeneous system where no roots are present.

**Figure 3** The chemical system trajectory, including the performed perturbations (only products are analyzed)

Cluster size	AAAA	AAAB	AABBA	ABBBBA	BAAB	BBBABA	Tci
2							40.34
3							38.42
3							36.19
4							29.10
3							24.10
2							22.98
4							22.58
2							21.41
3							18.93
5							18.92

(b)

**Figure 4** (a) The masks resulting from the chemical system analysis and (b) their corresponding Tc values. Note that the three masks whose Tc values outperform the other ones correctly identify the system's components (see text for details)

### Arabidopsis thaliana

It is possible to expand the analysis to BN derived from biological data of specific living beings. In this work we take advantage from the available data of the gene regulatory network shaping the developmental process of Arabidopsis thaliana: although the whole network is largely unknown, a certain subsystem has been identified as responsible for the floral organ specification. We will not enter here a discussion about the merits and limits of this simplified model, but we will take it "for granted" and we will apply our method to test whether it can discover significant MDSs.

The network is modeled by means of a BN described in (Chaos et al., 2006), which has 15 nodes and 10 different attractors (all fixed points): we therefore build a data series containing a number of repetitions of these attractors in proportion to their basins of attraction. In doing so it is possible to note that genes LUG and CLF are constantly active in all the attractors: this particular feature introduces a particular "noise" on CI analysis, by adding spurious cluster among the first positions. Indeed, it is possible to analytically demonstrate that the addition of constant nodes in clusters with high  $T_c$  leads again to other clusters with high  $T_c$  values: these additions nevertheless do not have particular biological meanings (the added elements do not introduce any variation), so the corresponding clusters can be memorized as "not significant".

The analysis clearly groups genes UFO and AP3, present alone on the best significant cluster and in all the following 20 most significant clusters. Note that the second significant cluster includes gene WUS: indeed, for biologists (Lenhard et al., 2001) (Lohman and others 2001) UFO and WUS are key inputs for determining the specific time and site where the combinations of gene activities considered in the developmental process are established, whereas AP3 is an important transcription factor. So, our analysis perceives the combination of a "sensor" (UFO) and of an influential "signaler" (AP3) as a single powerful dynamical engine, whose action can be tuned by WUS gene, demonstrating that it could highlight biologically interesting functional relationships.

**Figure 5** Floral network of *A. thaliana* (from (Chaos et al., 2006))

**Figure 6** Matrix illustrating the elements of the clusters (white in figure) identified by our analysis and their corresponding  $T_c$  values. Genes LUG and CLF are always constant along all the attractors and therefore their insertion in “active” MDSs can be excluded a priori (it is possible to analytically demonstrate that the addition of constant nodes in already existing clusters leads to cluster with high  $T_c$  values – but these additions do not seem have particular biological meanings)

## Conclusions

In this paper we introduced a system to identify candidate emergent mesolevel dynamical structures in dynamical networks. The main novelty of the present work, in comparison to previous application of the cluster index and of similar measures (Tononi et al. 1998) is that we used it to consider truly dynamical networks, and not only fluctuations around stable asymptotic states.

Future works will consider the application of the method to other important natural and artificial networks, an improved understanding of its working and the use of entropies taken at different times.

As examples of application we used time series of simple artificial systems and more complex data coming from catalytic reaction networks and biological gene regulatory systems (*A.thaliana*). The analysis performed by our system was able to identify correctly the MDSs, and we think it could suggest interesting new ways in dealing with artificial and biological systems.

Future work will consider the application of the method to other important natural and artificial networks, with the aim of deepen our understanding of its working principles and assessing its analysis power. In addition, we also plan to extend the definition of cluster index so as to take into account time relationships, for example by using of entropies taken at different times.

## Abstract

In spite of its significance for the adaptability of autonomous robotic swarms, the dynamic allocation and re-distribution of robots to tasks (i.e., role-allocation and role-switching behaviour) is still a design challenge in swarm robotics. This study investigates a simulated foraging scenario in which the variability of the environmental conditions requires that robots switch between two roles (i.e., foraging and nest-patrolling). To the best of our knowledge, this is the first simulation study that demonstrates that role-allocation and role-switching behaviour can be evolved using dynamic neural network controllers for robots with minimal communication capabilities. Initial analyses of the best evolved teams shed light on some of the characteristics and robustness of the strategies used by these teams to repeatedly face this task.

## Introduction

Swarm robotics is a particular approach to the design of multi-robot systems that finds its theoretical roots in recent studies in animal societies, such as ants and bees (Dorigo and Şahin, 2004). Despite noise in the environment, errors in processing information and performing tasks, and no global information, social insects are quite successful at performing group-level tasks (Anderson et al., 2001; Camazine et al., 2001). Based on the social insect metaphor, swarm robotics emphasises aspects such as decentralisation of the control, limited communication abilities among robots, use of local information, emergence of global behaviour and robustness. These properties are meant to facilitate the design of artificial systems scalable to group size, robust to noise, and adaptive to environmental changes.

Research in swarm robotics has been focusing on mechanisms to enhance the efficiency of the group through some form of cooperation among the individual agents. Complex forms of group cooperative responses can require task-partitioning (i.e., division of a collective task into individual sub-tasks) and/or task/role-allocation (i.e., allocation of sub-tasks/roles to different individuals, see Labella et al., 2006). The latter can be a dynamic and flexible process, in that the number of individuals engaged in any given task may need to continually change, as circumstances require. Hereafter,

we use the term role-switching or task-switching behaviour to refer to the process in which one or more agents leave their current activity to join a different one for the benefit of the team. In spite of its significance for the adaptability of the swarm, the autonomous and dynamic re-distribution of robots to tasks is still a design challenge. This study aims to investigate, in a simulated scenario, the conditions for the emergence of dynamic role-allocation and role-switching behaviour in teams of autonomous agents.

We face this challenge using the Evolutionary Robotics (ER) design method. ER is based on a bottom-up *modus operandi*, where variations are introduced at the genetic level, and selection is performed on the basis of the effects that genetic variations have on the global behaviour of the swarm. With respect to other design methods, ER does not require the designer to make strong assumptions concerning what behavioural and communication mechanisms are needed by the robots. Individual behavioural strategies and rules of actions are determined by the evolutionary process that favours (through selection) those solutions which improve an agent's and the group's ability to accomplish the collective task. The operational mechanisms of the best evolved teams can be *a posteriori* analysed to gain insight into the solutions of the collective problem.

Our long term goal is to apply ER to learning, i) the evolutionary dynamics underpinning the emergence of the role-allocation and role-switching behaviour in autonomous robots; ii) the nature of the individual mechanisms underlying the group response. This study is the first step in this direction. We investigate a scenario in which teams of homogeneous robots are required to split in foragers and nest-patrollers (i.e., robots that remain in the nest). The task demands that both roles are played, but according to different rules. Under one condition, foragers have to be more numerous than patrollers, while under the other the situation is the opposite. The results show that, such a relatively complex team behaviour can be obtained using only very limited means of interaction (i.e., infra-red sensors). Initial analyses of the best evolved teams shed light on some of the characteristics and robustness of the behavioural strategies used by

these teams to repeatedly face this task.

## Background and motivations

Several studies in swarm robotics are focused on issues related to the conditions that facilitate the emergence of behavioural specialisation among the robots. Many of these studies provide a comparative cost/benefit analysis of engineering specialisation by using heterogeneous teams (i.e., teams of robots with different individual controllers) versus dynamic and emergent forms of specialisation in homogeneous teams (i.e., team of robots that share the same individual controller, see Eiben et al., 2007; Luke and L.Spector, 1996; Bongard, 2000; Ijspeert et al., 2001; Quinn, 2001; Tuci and Trianni, 2012). From an evolutionary design perspective, homogeneous groups tend to imply a smaller search space than heterogeneous groups, and contrary to the latter they are not affected by the credit-assignment problem (i.e., the problem of divvying up among the team members the reward received through their joint actions, (see Panait and Luke, 2005)). Nevertheless, in those contexts in which partitioning the group task into different sub-tasks it is beneficial for the team, single controllers in homogeneous groups have to underpin behavioural skills required by the robots to undertake all the sub-tasks, as well as the decision making related to the allocation of robots to sub-tasks. The studies described in (Quinn et al., 2003; Ampatzis et al., 2009) showed that, in relatively small groups (2 to 3 robots), task-allocation and specialisation of the team members can be developed by breaking the homogeneity condition through the evolution of ritualised coupled behaviours subject to the effect of random noise inherent in sensory and motor hardware components. However, these studies looked at scenarios in which, once specialised, the agents do not need to reconsider their roles within the group. We know that in natural swarms task-allocation is quite dynamic and flexible, in that the number of individuals engaged in any given task continually changes as circumstances require (Gordon, 1996). Empirical evidence shows that internal factors, such as genetic and morphological differences among the workers, do not always account for the individual variability in task preferences. Single workers in various species of ants perform a variety of tasks, changing from one task to another by tracking contingent factors such as environmental stimuli, the number of agents currently engaged in other tasks, or the rate of interactions with other agents. For example, when a new food source suddenly become available to an harvester ant colony, which competes with other seed-eating species for food, ants previously engaged in other tasks will switch to foraging (Davidson, 1977).

Biologists are particularly interested in models focused on the evolution of emergent principles underpinning task-allocation. As stated in (Duarte et al., 2011), "... disappointingly few attempts have been made to develop realistic scenarios for how the mechanism underlying self-organised

division of labour evolve over the course of generation...". This is partially due to the limitations of classic methodologies at disposal of biologists. The authors in (Duarte et al., 2011) state that evolutionary models of division of labour tend to focus on the conditions in which specialisation is better than generalist strategies, ignoring the mechanism through which specialisation may arise. On the other hand, self-organisation models do not consider the evolutionary trajectories that may lead to task-allocation. Our long-term aim is to create models of the evolution of self-organised role-allocation and role-switching behaviour that can be used as "intuition-pump" for indicating potential evolutionary drivers and emergent behavioural rules capable of accounting for the collective behaviour of natural swarms (see Vassie and Morlino, 2012, for an epistemological account of robotic models). For example, biological evidence shows that behavioural specialisation in various insect societies evolve to minimise the costs of task-switching. Nevertheless, the fact that individuals switch tasks indicates that the evolution of task-allocation systems can not be merely the production of genetically and/or morphologically different individuals, each suited to a particular tasks. Empirically, little is still known about the selective pressures for task-switching behaviour. Robotics models can represent effective alternative methodological tools to investigate these issues. Our aim is to recreate these types of self-organised dynamics in homogeneous robotic swarms by evolving the individual mechanisms and rules of interactions/communication underpinning task-allocation and task-switching behaviour.

## The Simulation Environment

In the foraging scenario studied in this paper, the environment is a boundless arena with a nest and a foraging site. The nest is a circular area indicated by a green light, in which the colour of the floor is in shades of grey. The foraging site is also a circular area indicated by a red light, in which the colour of the floor is in a different shades of grey with respect to the nest. The colour of the arena floor is white. The radius of both the nest and the foraging site is randomly defined at the beginning of each trial in the interval [20cm, 30cm]. Both lights, the green one located in the nest and the red one located in the foraging site, are positioned 6cm above the floor and, when turned on, they are visible from everywhere within the arena. In each trial, the green light is placed at the centre of the nest. The red light is randomly placed anywhere within a semicircular area of 10cm radius centred in the centre of the foraging site. The centre of the nest is 1m far from the centre of the foraging site (see Fig. 1a)

The robots kinematics are simulated using a modified version of the "minimal simulation" technique described in (Jakobi, 1997). Our simulation models a e-puck robot, a 3.55cm radius cylindrical robot. It is provided with eight

Figure 1: (a) Experimental scenario (snapshot taken in *Env. A*, during *Phase 1*) showing the nest (dark grey circle), the foraging site (light grey circle), the five robots (white cylinders in the nest), and the lights (small circles above the nest and foraging site). (b) E-puck body-plan. The black circles refer to the position of the infra-red (IR), and floor sensor ( $F$ ) positioned facing downward on the underside of the robot (see Fig. 1b). The dotted lines indicate the robot's view with the three camera's sectors. (c) Robots starting position. The big circle represents the nest. The small circles are the robots, and the short black segments indicate the angle within which the robot orientation is chosen.

infra-red sensors ( $IR^i$  with  $i = \{0, \dots, 7\}$ ), which give the robot a noisy and non-linear indication of the proximity of an obstacle (in this task, an obstacle can only be another robot); a linear camera to see the lights; and a floor sensor ( $F$ ) positioned facing downward on the underside of the robot (see Fig. 1b). The IR sensor values are extrapolated from look-up tables provided with the Evorobot\* simulator (see Nolfi and Gigliotta, 2010). The  $F$  sensor can be conceived of as an IR sensor capable of detecting the intensity of grey of the floor. It returns 0 if the robot is on white floor, 0.5 if it is on light grey floor, and 1 if it is on dark grey floor. The robots camera has a receptive field of  $30^\circ$ , divided in three equal sectors, each of which has three binary sensors ( $C_i^B$  for blue,  $C_i^G$  for green, and  $C_i^R$  for red, with  $i = \{1, 2, 3\}$  indicating the sector). Each sensor returns a value which is 0 if no light is detected, 1 when a light is detected. The camera can detect coloured objects up to a distance of 1.5m. The robots can not see each other through the camera. The robot has left and right motors which can be independently driven forward or reverse, allowing it to turn fully in any direction. The robot maximum speed is 8cm/s.

### The Task and the Fitness Function

Teams comprising five simulated e-puck robots are evaluated in the context of a dynamic role allocation and role switching behaviour. By taking inspiration from the behaviour of social insects, the roles are nest patrolling and foraging (hereafter, we refer to them as *role P*, and *role F*, respectively). Roughly speaking, *role P* requires a robot to remain within the nest. *Role F* requires a robot to leave the nest for the foraging site, to spend a certain amount of time at the foraging site, and then to come back to the nest. A team is required to execute both roles simultaneously. Therefore, the robots have to go through a role-allocation phase in which they autonomously decide who is doing what, and then ex-

ecute their respective roles.

Moreover, the robots are required to be able to switch from one role to the other (i.e., role switching behaviour) due to the fact that they experience two different types of environment, *Env. A* and *Env. B*. In *Env. A*, *role F* is more important than *role P*. This means that in *Env. A*, a team maximises the fitness if the majority of robots (i.e., more than two robots) visits the foraging site and the minority (i.e., less than three robots) remains in the nest. In *Env. B*, *role P* is more important than *role F*. This means that a team maximises the fitness if the majority of robots (i.e., more than two robots) remains in the nest and the minority (i.e., less than three robots) visits the foraging site. Since a team, throughout its life-span, experiences twice both types of environment, not all the robots can specialise on a single role. The robots have to be able to play both roles and eventually to switch from one role to the other based on the current environmental condition and the roles allocated to the other team mates. How can a robot distinguish between *Env. A* and *Env. B*? The two types of environment can be distinguished by the intensity of grey colouring the floor in the nest site. In *Env. A*, the nest is coloured in dark grey and the foraging site in bright grey. In *Env. B*, the nest is coloured in bright grey and the foraging site in dark grey.

During evolution, each team undergoes a set of  $E = 2$  evaluation sequences (hereafter, e-sequence). An e-sequence is made of  $V = 4$  trials, in which the teams experience twice each type of environment in the following order: trial 1 *Env. A*, trial 2 *Env. B*, trial 3 *Env. A*, trial 4 *Env. B*. At the beginning of trial 1 of each e-sequence, the robots controllers are reset, and each robot is randomly placed within an area corresponding to a sector of the nest. The nest is divided in 6 sectors, and the robots are placed in sector 1 to 5, as illustrated in Fig. 1c. Each robot is randomly oriented in a way that the light can be within an angular distance of

$\pm 36^\circ$  from its facing direction (see Fig. 1c).

Each trial differs from the others in the initialisation of the random number generator, which influences the robots initial position and orientation, all the randomly defined features of the environment, and the noise added to motors and sensors (see Jakobi, 1997, for further details on sensors and motor noise). Within a trial, the team life-span is  $T=900$  simulation cycles (with 1 simulation cycle lasting 0.1s). Robots are frozen (i.e., don't move and do not contribute to the team fitness) if they exceed the arena limits (i.e., a circle of 120cm radius, centred in the middle point between the nest and the foraging site). Trials are terminated earlier if all the robots are frozen, or the team exceeds the maximum number of collisions (i.e., 10). In trials following the first one of each e-sequence (trial 2,3, and 4), the robots are repositioned only if the previous trial has been terminated earlier, or with one or more robot frozen.

Each trial is divided into three phases. During *Phase 1*, which lasts 12s, the green light is on and the red light is off. The robots are required to stay within the nest. During *Phase 2*, which can last from a minimum of 47,5s to a maximum of 52.5s, the red light is on and the green light is off. During *Phase 2*, a team is required to behave according to the rules of the task. That is, in *Env. A*, the majority of robots (i.e., more than two robots) has to visit the foraging site and the a minority (i.e., less than three robots) has to remain for the entire length of this phase in the nest. In *Env. B*, the majority of robots has to remain for the entire length of *Phase 2* in the nest and the minority has to visit the foraging site. A robot is considered having visited the foraging site if, during *Phase 2*, it spends more then 100 consecutive time steps within the foraging site. During *Phase 3*, which starts at the end of *Phase 2* and terminates at the end of the trial, the green light is on again and the red light is off. The robots that were foraging during *Phase 2* are required to return in the nest to rejoin their team mates.

The fitness of a genotype is its average team evaluation score after it has been assessed for two e-sequences (i.e., for a total of 8 trials). In each trial ( $v$ ) of each e-sequence ( $e$ ), the team is rewarded by an evaluation function  $F_{ev}$  which corresponds to:  $F_{ev} = ((PH^1 \times PH^3) + PH^2) \times PEN$ .  $PH^1 \in [0, 1]$  is computed during *Phase 1*, and it corresponds to the robot average proportion of time steps “inside” the nest.  $PH^2$  is computed during *Phase 2*.  $PH^2 = 5$  if the robots follow the rules of the task (see above). If the team does not behave according to the rules of the task, then  $PH^2$  corresponds to i) the proportion of foraging robots multiplied by two, in *Env. A* ii) the proportion of robots remained in the nest multiplied by two in *Env. B*.  $PH^3$  is computed during *Phase 3*.  $PH^3 = 2$  if all the robots terminate the phase within the nest.  $PH^3$  corresponds to the proportion of robots that terminated the trail within the nest, otherwise.  $PH^3$  is set to 1 if the trial is terminated before a team reaches *Phase 3*. The team collision penalty

Figure 2: The neural network.

$PEN$  is inversely proportional to the number of collisions, with  $PEN = 1$  with no collisions, and  $P^a = 0.4$  with 10 collisions in a trial; The average team evaluation score is  $F = \frac{1}{E} \frac{1}{V} \sum_{e=1}^E \sum_{v=1}^V F_{ev}$ .

### Controller and the Evolutionary Algorithm

The robot controller is composed of a continuous time recurrent neural network (CTRNN) of 11 sensor neurons, 4 inter-neurons, and 4 motor neurons (see Beer and Gallagher, 1992). The structure of the network is shown in Fig. 2. The states of the motor neurons are used to control the speed of the left and right wheels as explained later. The values of sensory, internal, and motor neurons are updated using equations 1, 2, and 3.

$$y_i = gI_i; \text{ for } i \in \{1, \dots, 11\}; \quad (1)$$

$$\tau_i \dot{y}_i = -y_i + \sum_{j=1}^{15} \omega_{ji} \sigma(y_j + \beta_j); \text{ for } i = \{12, \dots, 15\}; \quad (2)$$

$$y_i = \sum_{j=12}^{15} \omega_{ji} \sigma(y_j + \beta_j); \text{ for } i = \{16, \dots, 19\}; \quad (3)$$

with  $\sigma(x) = (1 + e^{-x})^{-1}$ . In these equations, using terms derived from an analogy with real neurons,  $y_i$  represents the cell potential,  $\tau_i$  the decay constant,  $g$  is a gain factor,  $I_i$  with  $i = \{1, \dots, 11\}$  is the activation of the  $i^{th}$  sensor neuron (see Fig. 2 for the correspondence between robot's sensors and sensor neuron),  $\omega_{ji}$  the strength of the synaptic connection from neuron  $j$  to neuron  $i$ ,  $\beta_j$  the bias term,  $\sigma(y_j + \beta_j)$  the firing rate (hereafter,  $f_i$ ). All sensory neurons share the same bias ( $\beta^I$ ), and the same holds for all motor neurons ( $\beta^O$ ).  $\tau_i$  and  $\beta_i$  with  $i = \{12, \dots, 15\}$ ,  $\beta^I$ ,  $\beta^O$ , all the network connection weights  $\omega_{ij}$ , and  $g$  are genetically specified networks' parameters. At each time step, the output of the left motor is  $M^L = f_{16} - f_{17}$ , and the right motor is  $M^R = f_{18} - f_{19}$ , with  $M_L, M_R \in [-1, 1]$ . Cell potentials are set to 0 when

the network is initialised or reset, and equation 2 is integrated using the forward Euler method with an integration time step  $\Delta T = 0.1$ .

A simple evolutionary algorithm using linear ranking is employed to set the parameters of the networks (Goldberg, 1989). The population contains 100 genotypes. Generations following the first one are produced by a combination of selection with elitism, recombination, and mutation. For each new generation, the three highest scoring individuals (“the elite”) from the previous generation are retained unchanged. The remainder of the new population is generated by fitness-proportional selection from the 60 best individuals of the old population. Each genotype is a vector comprising 87 real values (76 connections, 4 decay constants, 6 bias terms, and a gain factor). Initially, a random population of vectors is generated by initialising each component of each genotype to values chosen uniformly random from the range  $[0,1]$ . New genotypes, except “the elite”, are produced by applying recombination and mutation. Each new genotype has a 0.3 probability of being created by combining the genetic material of two parents. During recombination, one crossover point is selected. Genes from the beginning of the genotype to the crossover point is copied from one parent, the other genes are copied from the second parent. Mutation entails that a random Gaussian offset is applied to each real-valued vector component encoded in the genotype, with a probability of 0.04. The mean of the Gaussian is 0, and its standard deviation is 0.1. During evolution, all vector component values are constrained to remain within the range  $[0,1]$ .

## Results

Our objective is to design neuro-controllers for homogeneous teams of robots required to exhibit the following skills: dynamic role-allocation, and role-switching behaviour. This means that teams have to be capable of dynamically allocating roles to robots and simultaneously executing both roles in each trial. Moreover, not all the robots can specialise in a single role (i.e., playing only a single role throughout an e-sequence). This is because there are two different types of environment: *Env. A*, in which the majority of the robots has to play *role F*; and *Env. B*, in which the majority of the robots has to play *role P*. The robots (at least one) have to switch role between consecutive trials for the majority to be distributed as required by the task.

10 evolutionary runs, each using a different random initialisation were carried out for 2500 generations. Seven evolutionary runs managed to generate teams with the highest fitness score (data not shown<sup>1</sup>). In order to have a better estimate of the behavioural capabilities of the evolved teams, we post-evaluated, for each run, the fittest team of each generation for the last 500 generations. The post-evaluation test

<sup>1</sup>See <http://users.aber.ac.uk/elt7/suppPagn/ECAL2013/suppMat.html> for further methodological details, graphs and movies of the best teams.

Figure 3: Graph showing the performances of the best teams from 8 different evolutionary runs, re-evaluated for 64 sequences. For each team, the number below the bars refers to the average score  $F$ . The four bars in shades of grey (from black to light grey) indicate the % of success in each of the four temporal sections (or trials) of an e-sequence, respectively. The fifth bar (the white one) indicates the % of successful e-sequences out of 64.

consists of 64 e-sequences per team (for a total of 256 trials, 4 trials times 64 e-sequences). The performance of each team is measured using the metrics  $F$  illustrated above, with  $E = 64$ . For each run, the team with the highest average re-evaluation score  $F$  is assumed to be an adequate measure of the success of the run.

The graph in Fig. 3 shows for each best team, the fitness ( $F$ ), the success rate (%) in each temporal section (i.e., trial) of the e-sequence (i.e., black bars for the first trials, dark grey bars for the second trials, medium grey bars for the third trials, and light grey bars for the fourth trials), and the percentage of successful e-sequence out of 64 (see white bars). An e-sequence ( $e$ ) is considered successful if a team manages to get the highest score ( $F_{ev} = 7$ ) in each of the four trials ( $v$ ). Note that, the results of the worst two runs have been omitted from Fig. 3 because the percentage of successful e-sequence of the best teams was 0.

The numbers just below the bars in Fig. 3 refers to the average fitness score of each team. Four teams (team n. 1, 2, 3, and 6) managed to get an average fitness score quite close to the optimum  $F = 7$ , with the team generated by run n. 3 (hereafter, team n. 3) being the most successful. The bars in the graph explain the meaning of these fitness scores in term of teams’ performance and robustness. For example, team n. 1, 2, 3, and 6, have a relatively high success rate in each of the four temporal sections of the e-sequence (see black to light grey bars in Fig. 3, for team n. 1, 2, 3, 6). Nevertheless, these scores do not necessarily correspond to a high percentage of successful e-sequences. Team n. 1, 2, 6 have a percentage of successful e-sequence below 70% (see white bars in Fig. 3, for team 1, 2, and 6). Team n. 3, instead, manages to successfully complete about 80% of the

64 post-evaluation e-sequences, proving to be quite robust and effective. As shown in Table 1, team 3 is also the only team for which unsuccessful e-sequences are all caused by only a single unsuccessful trial.

To summarise, several best evolved teams look quite effective in repeatedly solving individual temporal sections of the task (i.e., single trials), even if none of the best teams proved to be 100% successful. One evolutionary run (n. 3) managed to generate several successful and robust teams, with the best of them capable of executing about 80% of successful e-sequences at the post-evaluation test. The performances of best evolved teams from other evolutionary runs are significantly reduced if evaluated with respect to the percentage of successful e-sequences. This data indicates that, for most of the teams, the evolutionary scores have been an overestimation of the effective behavioural capabilities of the teams. We will further discuss the reasons of the post-evaluation performance drop of some of the best evolved teams in the next section.

### Analysis of the best evolved team

In this Section, we show data collected during the post-evaluation test aimed to illustrate some of the features of the best evolved team (i.e., team n. 3). In particular, we show some qualitative data referring to role-switching behaviour. Recall that, an e-sequence is made of 4 trials, during which the robots controller is not reset. In an e-sequence, a team experiences both types of environment in the following order: trial 1 *role F*; trial 2 *role P*; trial 3 *role F*; trial 4 *role P*. Role-switching is a robot's behaviour that happens between two consecutive trials. Within a single trial, a robot can only play either *role P* or *role F*. A role-switching event refers to any change of role from *role P* to *role F* or vice-versa.

How many robots of team n. 3 switch role during an e-sequence? Due to the nature of the task, a team can employ different strategies with respect to role-switching. For example, a strategy with relatively small amount of role-switching behaviour is one in which one robot systemati-

Table 1: Table showing, for each team, num. of unsuccessful e-sequence with failure in: 1 trial (col. 2), 2 trials (col. 3), 3 trials (col. 4), 4 trials (col. 5). Best team in grey.

Team n.	Num. trial failed			
	1	2	3	4
1	14	6	0	0
2	23	11	1	0
3	13	0	0	0
4	8	16	29	9
5	7	20	25	8
6	23	3	2	0
7	22	19	12	2
8	15	29	15	2

Figure 4: Graphs showing, for team n. 3, the different behavioural strategies (indicated by the four 2-tuples on the x-axis) and their frequencies recorded in the 51 successful e-sequences of the re-evaluation test. On the x-axis, the first element of each 2-tuple refers to the number of role-switching event and the second element refers to the number of robots.

cally switches role at the beginning of a trial (for a total of 3 switches), two robots systematically play *role F*, and two robots systematically play *role P*. A strategy with a significant amount of role-switching behaviour is one in which all the robots change roles in response to any type of environmental change. Fig. 4 shows all the behavioural strategies of team n. 3 observed among all the 51 successful e-sequences recorded at the post-evaluation test. A behavioural strategy is described by 4 2-tuples, in which the first element of each 2-tuple refers to the number of role-switching event and the second element refers to the number of robots. For example, the first bar in Fig. 4 refers to the strategy in which during an e-sequence, 3 robots switch role two times, and 2 robots switch role three times. This is the strategy employed more frequently by team n. 3 during successful post-evaluation e-sequences. However, we can see that this team employs up to 6 different strategies, all of them characterised by the fact that all the robots switch role at least once during a successful e-sequence. The team relies on a variety of strategies which are highly dynamics with respect to role-switching behaviour. Thus, the evolutionary conditions characterised by our experimental scenario are sufficient to generate controllers that are plastic enough to avoid behavioural specialisation (i.e., robots that play only a single role throughout an entire e-sequence).

How much is the role that a robot play determined by the characteristics of the environment? The graph in Fig. 5 shows, for each robot of the best evolved team (n. 3), the

Figure 5: Graph showing, for each robot of team n. 3, the percentage of successful post-evaluation e-sequences, in which the robot plays a different role in different trials presenting the same type of environment. Black bars refers to *Env. A*, white bars to *Env. B*.

percentage of successful e-sequences, at the post-evaluation test, in which the robot plays a different role in trials associated to the same type of environment. This graphs indicates that the type of environment experienced by a robot is not the only cue that determines the role a robot plays within a trial. This is because, for both *Env. A* and *Env. B*, the robots do not necessarily play the same role in different trials associated to the same type of environment. The simple rule “one role for each type of environment” does not systematically apply to any robot of the team n. 3. There is a certain amount of variability among the robots, with robot 1 (i.e., the robot initialised in sector 1, see Fig. 1c) being the most reluctant to play different roles in different trials of an e-sequence presenting the same type of environment (see Fig. 5). Nevertheless, this evidence suggests that the roles are genuinely determined by a combination of factors. In particular, the physical interactions among the robots bring forth contingent phenomena that, biased by the current environmental condition, guide the role-allocation process.

Without further evidence, it is premature to speculate on the operational mechanisms that guides the decision process in this scenario. In similar studies, in which homogeneous teams have been evolved to solve dynamic role-allocation tasks using infra-read sensors as means for communication, the decision making process turned out to heavily rely on the noise injected into the simulation (e.g., Ampatzis et al., 2009). It is likely that, even in our scenario, the robots exploit the noise to break the symmetries due to the homogeneity of the system, and to “diverge” on different roles. However, this scenario differs from those described in the studies above mentioned for two main features: first, the robots are required to repeatedly go through the decision making process, without the robot controllers being reset. Thus, from a functional point of view, the symmetry condition of the robots controller applies only to trial 1. Second,

variable environmental structures and the robots interactions have to equally contribute to the dynamic allocation of roles to robots. This means that, the noise may not be so important in guiding the decision making as it turned out to be in the above mentioned studies.

The relative positions of the robots at the beginning of each trial can potentially be another element that influences the role-allocation process. By visually inspecting the team behaviour, we noticed that most of the best evolved strategies are particularly sensitive to the variability in the initial relative positions of the robots. Too much variability is highly disruptive. Another evidence in favour of the significance of the “initial relative positions” hypothesis for the role allocation process can be found in Fig. 3. The graphs shows that the best three teams (n. 1, 3, 6) did worst in the first temporal section (trial) than in the following three sections at the post-evaluation test (compare black with all the other bars in Fig. 3, for team n. 1, 3, 6). Recall that, in trials following the first one, the robots can position themselves, through their movement, in a way to facilitate the execution of the task. In the first trial of each e-sequence the robots are pseudo-randomly positioned. The robots’ positioning algorithm has been intentionally designed to introduce some variability into the system. However, it seems that, even the best evolved strategy can only cope with a limited portion of this variability. Future work and analysis on the operational mechanisms used by the robots to allocate role may shed light on whether and the extent to which the robots relative position at the beginning of the trial has an impact on the performance of the team, and on the role that each robot play within the team. However, it seems plausible to think that the sensitivity of the best evolved teams to the variability in the robots’ initial relative position can account for the fitness drop observed between evolution and post-evaluation.

## Conclusion

In this study, we have investigated the evolutionary conditions that facilitate the emergence of role-allocation and role-switching behaviour in teams of homogeneous robots. To the best of our knowledge, this is the first simulated study in which: i) role-allocation and role-switching behaviour are both required for the benefit of the team. ii) role-allocation and role-switching behaviour are evolved in team of more than 3 agents; iii) a relatively complex team’s behaviour, based on a different distribution of robots-to-roles, is obtained using only infra-red sensors as means for interaction.

We consider this study the first step towards the development of swarm robotics models that could shed light on the evolution of self-organised role-allocation and role-switching behaviour. Similarly to other swarm robotics studies, we are motivated by engineering and biological objectives. From an engineering perspective, our objective is to look at task/role-allocation and task/role-switching behaviour in order to generate design principles that preserve

the adaptability and flexibility of both the system components and of the resulting processes. With respect to this, the results of this study demonstrate that a task requiring complex group response in simulated agents with limited sensory and communication capabilities can be solved by teams of homogeneous robots controlled by dynamic neural network synthesised by artificial evolution.

From a biological perspective, we aim at generating new insights into the general properties of large scale distributed natural systems. In particular, this project aims at providing a principled understanding of the temporal development of task/role-allocation and task/role-switching behaviour by designing models that look at the effect of evolution on operating and design principles. Further work and analysis of the working principles of the evolved solutions is certainly required to be able to understand how our simulated teams solve the task, and how this can help us to understand natural swarms. However, at first glance, we can already mention a couple of phenomena that seem to play a significant role for the evolution and development of self-organised role-allocation and role-switching behaviour. The first element is the way in which the robots access and leave the nest. In our scenario, the robots have been left free to move in and out the nest from any directions. However, the best evolved strategies are based on movements which induce all the foragers to exit and re-enter the nest from a specific limited area. This suggests that structural properties of the nest may interfere and maybe facilitate the adaptive re-distribution of agents-to-roles. Another element is the amount of environmental variability the system can cope with. Our robots, which communicated only through infra-red sensors, bring forth strategies that seem quite fragile with respect to various sources of variability, such as the cardinality of the team, the distance between nest and foraging site, the length of a trial, the order in which the different environmental conditions are experienced, etc. Future work will concentrate on the investigation of alternative means of communication that could strengthen the effectiveness of the self-organised re-distribution of agents-to-roles.

## Abstract

Simple models of complex phenomena provide powerful insights and suggest low-level mechanistic descriptions. The Earth system arises from the interaction of subsystems with multi-scale temporal and spatial variability; from the microbial to continental scales, operating over the course of days to geological time. System-level homeostasis has been demonstrated in a number of conceptual, artificial life, models which share the advantage of a thorough and transparent analysis. We reintroduce a general model for a coupled life-environment model, concentrating on a minimal set of assumptions, and explore the consequences of interaction between simple life elements and their shared, multidimensional environment. In particular stability, criticality and transitions are of great relevance to understanding the history, and future of the Earth system. The model is shown to share salient features with other abstract systems such as Ashby's Homeostat and Watson and Lovelock's Daisyworld. Our generic description is free to explore high-dimensional, complex environments, and in doing so we show that even a small increase in the environmental complexity gives rise to very complex attractor landscapes which require a much richer conception of critical transitions and hysteresis.

## Introduction

The principle that environmental factors affect life is evident throughout the biosphere both regionally and globally, and throughout Earth's history (Gaston 2000). Variables such as temperature and soil or atmospheric composition determine whether an organism can proliferate, and populations will develop to some resource limited level. Climatic shifts between, for example, greenhouse and icehouse states are accompanied by mass extinction (Haywood 2004). Indeed this principle is at the core of environmental niche modelling, where the distribution of species in the space of significant environmental factors, their *realized-niche*, is used to predict the spatial species distribution (Thomas et al. 2004). The influence of life on its environment however, and whether it is expected to have a stabilising, or destabilising effect is less clear. Lovelock and Margulis's (1974) original "Gaia Hypothesis" focused on the extent to which the emergence of life has promoted a self-regulating, or homeostatic system. In this work we consider the ability of a coupled life-

environment system to generate stabilising feedback loops in increasingly complex environments under a minimal set of assumptions.

The Gaia-hypothesis proposes that life may self-organise into complex, self-regulating systems with maintain the habitability of their environment and at the higher level contribute to regulation of variables globally conducive for life to flourish. Controversy followed as it is unclear how regulatory mechanisms might emerge without the need for system-wide cooperation which would contradict the principle of natural selection at the species level (Doolittle 1981). Watson and Lovelock's (1983) "Daisyworld" took the first step towards addressing this with an abstract coupled life-environment model whose biota consists of two species of daisy which exert a unidirectional force on their shared environment, reduced to a single temperate variable. Black daisies absorb a large amount of energy, and have a warming effect compared to white daisies which have a high albedo and an overall cooling effect. If the species are organised such that black daisies out-compete white daisies at low temperatures, the model shows that infinitesimally differentiated species can establish *reign-control* over their environment (Harvey 2004); a small reduction in global temperature allows the black absorptive daisies to proliferate and visa-versa for increases in temperature. In this way, each species holds a reign, opposing changes in one direction such that the planetary temperature is not just stable, but robust to a range of external perturbations. There have been a number of extensions and developments of the original Daisyworld model (see Wood et al. (2008) for a review), some of which has been undertaken within the field of artificial life. Dyke et al. (2007) for example allow external perturbation to vary on timescales comparable to changes in the biota, while Williams and Noble (2005) extend the model to enable stochastic evolution of daisy species.

We aim to address two short-comings of this model in detail. Firstly, while useful in its transparency, the behaviour of such a one-dimensional dynamical system is extremely limited. Iconic phenomena such as hysteresis loops are a common metaphor for transitions in very complex systems,

although do not take into account the additional degrees of freedom of high dimensional systems which may exhibit cyclical, complex or chaotic behaviour, inaccessible to such a simple metaphor. It is therefore unclear the extent to which this picture fits such high-dimensional systems. On the other hand, while more complicated many-body systems benefit from a much richer zoo of emergent behaviours, it typically comes at the expense of transparency, exchanging generality for a more faithful representation of a specific system. Along with increasingly complex environments, the relevance of the reign-control mechanism to very much larger populations of diverse biotic elements is unclear. Daisyworld does not address the mechanism by which the pair of antagonistic species might emerge. While later work makes clear that the mechanism is not unique to a two-species model, a persistent theme of such models is that they are in some sense *designed* (Lenton 1998).

Along with these key points, we explore the nature of critical transitions or “regime shifts” (Williams and Lenton 2010). We utilize a Daisyworld-type model first introduced in Dyke (2010) then extended in Dyke and Weaver (2013) in order to assess to what extent iconic phenomena such as hysteresis loops, which are a common metaphor for transitions in very complex systems, are appropriate when considering higher dimensional systems. We will show that even a small increase in the environmental complexity generates surprisingly detailed, and complex attractor landscapes. Understanding the way in which we traverse the space of environmental variables calls for a richer conception of critical transitions and hysteresis. In short we find that some critical transitions have little impact on system behaviour while others can produce large changes from states which may not be recoverable, resulting in asymmetrical transitions. Importantly, there appears no immediate way in which to differentiate between them and thus our results may be interpreted as urging caution for the use of early warning signals for complex systems.

### Model formulation

Dyke’s (2010) “Daisystat” model in single environmental variable mode can be understood as a simplified Daisyworld model, very similar to the Artificial Life model of McDonald-Gibson et al. (2008). A population of simple organisms is affected by their environment such that they thrive in the vicinity of their ecological niche, and in turn influence the environment through simple, linear feedbacks. The key differences between the Daisystat model, and Daisyworld are that Dyke’s (2010) enables the description of higher dimensional environments and rather than prescriptive feedbacks, the model employs random life-environment interactions.

Throughout this work, we describe the distribution of biota through  $K$  variables,  $\alpha$ , denoting the overall activity of individual elements, or populations, influenced by the state

Figure 1: In the simplest case, biotic elements,  $\alpha$ , have an increasing or decreasing,  $\omega$ , effect on their environment  $E$ . In turn, they are only abundant over a finite range of the environmental variables, centred on their fundamental niche,  $\mu$ .

of their shared environment, represented the  $N$  variables in the vector  $E$ , where we have used boldface notation to denote vectors, and will reference individual elements with subscripted indices.

$$\mathbf{X} = \begin{bmatrix} X_1 \\ X_2 \\ \vdots \\ X_n \end{bmatrix}$$

The first principle assumption is that components of the biota are only significantly abundant, or active, in the vicinity of their ideal environmental conditions, or *niche*. The second assumption is that the environment is itself influenced by the biota; environmental variables may be decreased or increased by the individual biotic elements, through consumption, excretion or some other process with no bias towards positive or negative feedback. In essence, the model consists of these two principle assumptions, illustrated by Fig. 1. This section elaborates on these assumptions, along with their consequential behaviour.

**i) Environment affects life** Each element of the biota only has a significant presence in a narrow range of environmental conditions wherein it may proliferate, respire, or is otherwise active. As environmental conditions depart this niche, the activity is reduced until the population recedes or becomes dormant such that its presence is negligible. While many species may occupy a wide range of niches, we may add an additional constraint that there is a limited range of environmental conditions which are conducive to life at all, such as the conditions to maintain liquid water. This confines the niche for any population to some volume of the space of environmental variables within which life may exist, known as the *essential range* (Ashby 1952), given by the range  $[0 : R]$  for simplicity.

A simple choice of function to describe the changes in the

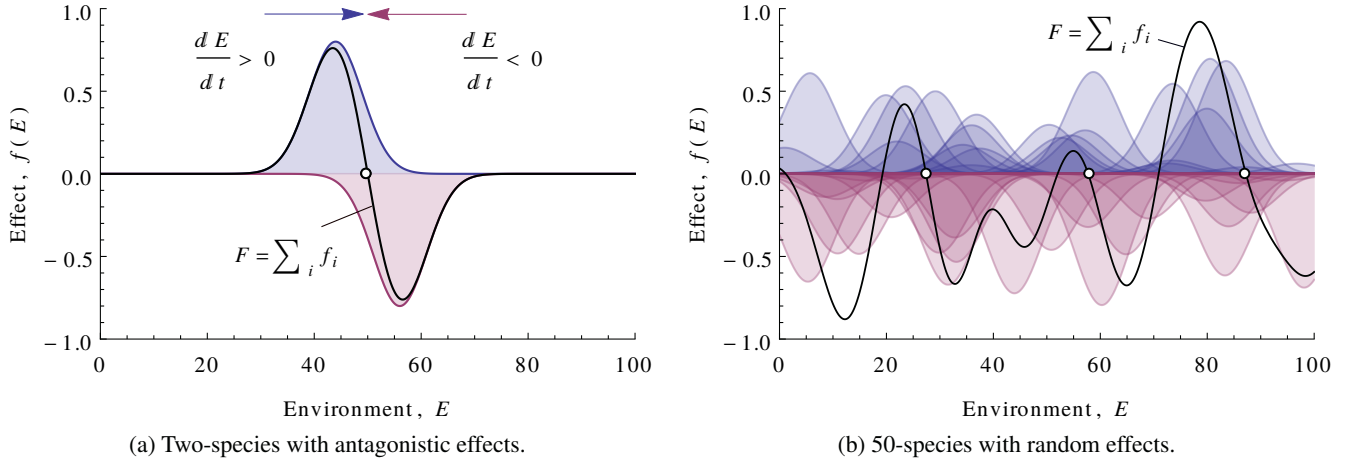

Figure 2: Activity of individuals with increasing (blue) and decreasing (red) effects on their environment, along with the net effect  $F(E) = \sum_i f_i(E)$ . Fixed points, shown by open circles, occur where the sum of individual effects is exactly zero. Fig. 2a is analogous to Daisyworld and illustrates the reign-control mechanism, along with a single fixed point. Fig. 2b shows large numbers of species with random effects (with no preference for negative, or positive feedback), demonstrating the emergence of such points *by chance*.

Figure 3: The two environmental variable model with no external perturbation,  $\mathbf{P} = \mathbf{0}$ . Points indicate the position of stable fixed points, where  $\mathbf{F}(\mathbf{E}) = \mathbf{0}$  and  $\nabla \mathbf{F} < \mathbf{0}$ . Shaded regions show the basin of attraction for each point indicating that a model initiated within the region will arrive at the fixed point. Increasingly positive or negative perturbations will influence the shape of the attractor space such that some attractors will disappear, and new attractors may even emerge, resulting in rapid transitions.

biota would be a linear relaxation towards some steady-state;

$$\tau_\alpha \frac{d\alpha_i(t)}{dt} = \alpha^*(\mathbf{E}, \boldsymbol{\mu}_i) - \alpha_i(t) \quad (1)$$

where  $\tau_\alpha$  defines the timescale of changes in the population  $\alpha_i(t)$  towards its steady-state value,  $\alpha^*(\mathbf{E}, \boldsymbol{\mu})$  is the steady-state distribution about the individual niche  $\boldsymbol{\mu}_i$ . It has been shown that the specific choice of this distribution is unimportant providing it has a well defined variance (Dyke and Weaver 2013). In this instance we choose a Gaussian distribution with characteristic width  $\sigma_E$ , centred on  $\boldsymbol{\mu}$  chosen randomly in the interval  $[0 : R]$ , the essential range.

$$\alpha^*(\mathbf{E}, \boldsymbol{\mu}) = \exp\left(-\frac{|\mathbf{E} - \boldsymbol{\mu}|^2}{2\sigma_E^2}\right) \quad (2)$$

**ii) Life affects environment** On the other hand, the biota has an effect on their shared environment. Individual populations may modify environmental variables independently, having either an increasing or decreasing effect. Black daisies in Watson and Lovelock's (1983) Daisyworld for example absorb a large amount of radiation compared to white daisies, having an increasing effect on temperature. In the simplest case, the biota has an effect,  $\mathbf{f}$ , in proportion to their activity

$$\mathbf{f}_i(t) = \omega_i \alpha_i(t) \quad (3)$$

where  $\omega_i$  is the effect of an individual on the environment  $\mathbf{E}$ , chosen randomly from the interval  $\pm 1$ . The net effect of the biota on the environment,  $\mathbf{F}$ , is simply found by summing individual contributions

$$\mathbf{F}(t) = \sum_{i=1}^K \mathbf{f}_i(t). \quad (4)$$

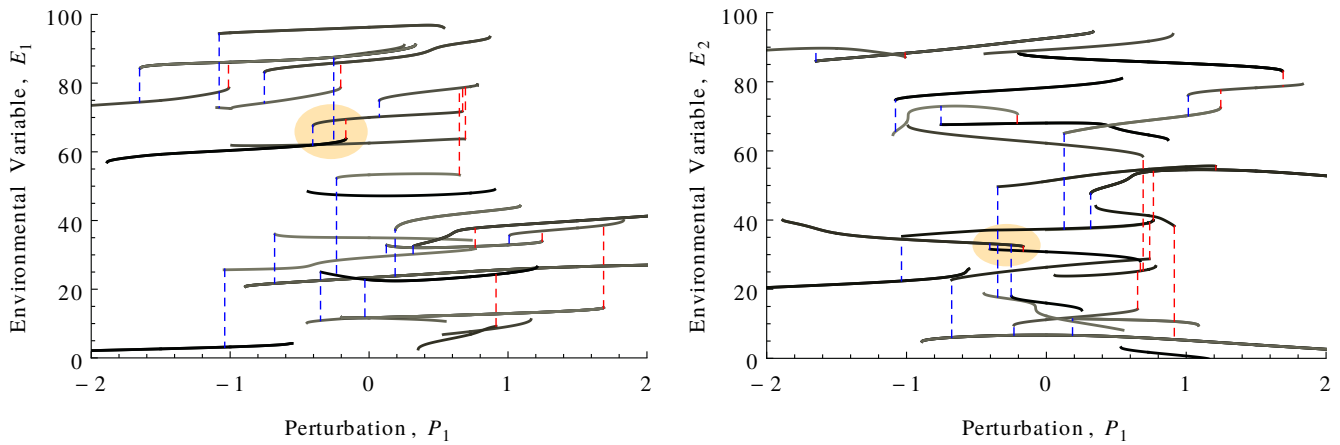

Figure 4: The states and transitions which exist in a two-dimensional environment model for a range of  $P_1$ , where  $P_2 = 0$ . States are shaded randomly to help differentiate them, and end abruptly where states become unstable and transition outside the essential range, as opposed to towards another stable state. Transitions to other states are colored red and blue where the transition is encountered by increasing and decreasing perturbation respectively. Importantly, not all transitions are symmetrical. Several transitions occur from states which may not be recovered by trivially applying an opposing perturbation as would be expected in the case of a one-dimensional system. Indeed some states undergo no transitions at all, besides those which would drive the system outside the essential range. The basins of attraction which lead to the hysteresis loop marked are represented by Fig. 5.

Additionally, each of the environmental variables may be affected by some external abiotic perturbing force,  $\mathbf{P}$ . In the original Daisyworld model, the single environmental variable was temperature, and the perturbing force was insolation, the influence of Daisyworld's star. Other perturbing effects may include flux of chemicals or gasses, such as by volcanic or anthropogenic emission. The net change in the environment is the sum of these features

$$\tau_E \frac{d\mathbf{E}(t)}{dt} = \mathbf{P} + \mathbf{F}(t) \quad (5)$$

where  $\tau_E$  is the characteristic timescale for changes in environmental variable  $i$ , chosen to be equal between variables for convenience, and  $F_i$  is the sum of effects from the biota.

It is important to establish the relationship between the times scales of changes in the biota,  $\tau_\alpha$ , and their shared environment,  $\tau_E$ . Progress towards establishing the behaviour of such models has been demonstrably simpler by assuming a separation of timescales  $\tau_E \gg \tau_\alpha$ . In the Daisyworld model for example, this leads directly to an analytical solution (Weaver and Dyke 2012). In this limit, the populations  $\alpha_i(t)$  quickly adjust to their steady-state values  $\alpha_i^*(\mathbf{E}, \boldsymbol{\mu}_i)$ , removing the time dependence in  $\mathbf{F}(t) \rightarrow \mathbf{F}(\mathbf{E})$ . Furthermore, the summed effect  $\mathbf{F}$  is normalised to have a variance  $\sigma_F^2 = 1$  for convenience.

Similarities with Watson and Lovelock's (1983) Daisyworld are clear for simple, one-dimensional environments. Fig. 2 illustrates the individual effects of the individual populations,  $f_i$ , along with the total effect,  $F$ . Fig. 2a shows the Daisyworld control mechanism, so called reign-control.

The two populations exert opposing forces on their environment, where the population with a positive effect is abundant at low ranges, while the negative effect dominates for larger values. This system naturally finds stability at a point where these effects are exactly in balance, somewhere between the niches of the opposing populations. Fig. 2b shows 50 *random* populations (random in both their niche, and influence of the environment). Importantly, fixed points occur where the net effect,  $F$ , crosses zero, and are furthermore stable only when the gradient is negative. In the case of Daisyworld, it may be remarked that the single fixed point is prescribed in the model formulation. However, previous work has concentrated on the emergence of these points from interactions between many populations and their shared environment *by chance*, finding them to be a generic property of such models, largely independent of the dimensionality of  $\mathbf{E}$  (Dyke and Weaver 2013).

## Higher Dimensions

Typically, illustrations of hysteresis involve a single variable. Such examples however bely the much more colourful behaviour which emerges in higher dimensional systems. Firstly, it has been shown that the expected number of fixed points increases exponentially with the dimensionality of the environment (Dyke and Weaver 2013), resulting in very many more stable states. This may be contrary to intuition as a fixed point must be stationary in all dimensions simultaneously, and appears exponentially unlikely with more complex environments. However, this is opposed by the increase

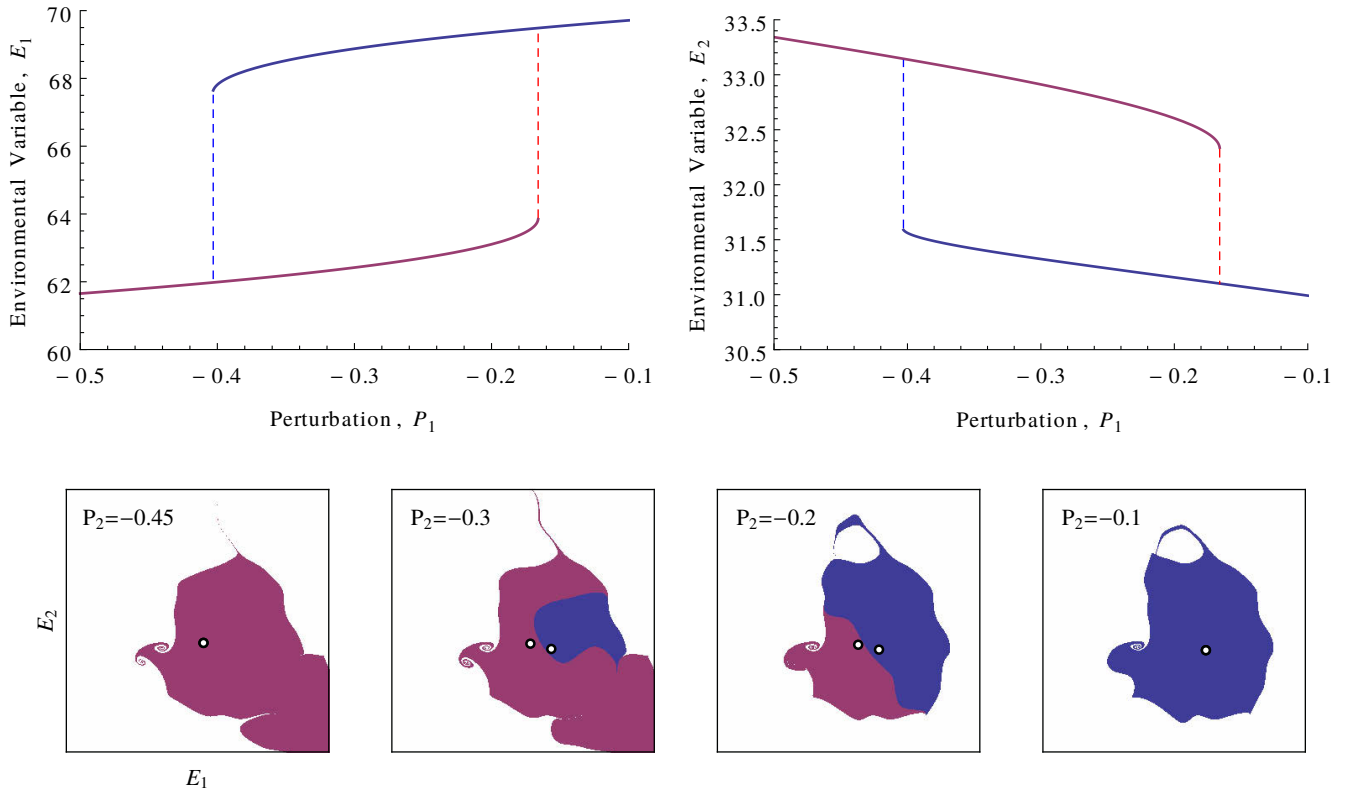

Figure 5: Colored regions correspond to the basins of attraction of the two fixed points (shown by open circles) highlighted in Fig. 4. As the perturbation is varied, one fixed point vanishes, and its basin of attraction is encompassed by that of the other fixed point, resulting in a transition. In this instance, the transition is roughly symmetrical and the previous state may be recovered by reversing the perturbation.

in volume of the environment  $E$ , which enables many more configurations of the biota. Here, we demonstrate the complicated network of transitions between these states with increasing or decreasing perturbations. Fig. 3 shows a randomly initialised two-dimensional system of fixed points for the model subjected to no external perturbation. The response of these fixed points to perturbation is demonstrated by Fig. 4, showing the same two-dimensional system for increasing and decreasing perturbations in one direction. The complicated behaviour is perhaps best interpreted in terms of attractors, where transitions occur when a basin of attraction is fully succeeded by another, illustrated by Fig. 5 for a roughly symmetrical transition between two states. Some notable features of Fig. 4 include

**Density of states** The stable states consistent with a particular driving force exhibits great diversity. Rather than bistability, Fig. 4 shows over a dozen stable states at a given perturbation. Furthermore Dyke and Weaver (2013) finds the density of stable states increases exponentially with environmental complexity. It is not unreasonable to expect higher dimensional environments to house hundreds of vi-

able stable states. Another interesting observation of Fig. 4 is that the density of stable states diminishes (exponentially) with increasing perturbation strength. In a one dimensional system for example, the mean number of stable states in a unit interval is given by

$$n = \frac{1}{2\sqrt{2\pi}\sigma} \exp\left(-\frac{P^2}{2}\right) \quad (6)$$

while is illustrated in Fig. 6. It is intuitive that the summed contributions of random, uncorrelated effects is Gaussian distributed, and therefore the density of points with a strong enough effect to oppose increasing perturbations decreases.

**Step size** The geological record is punctuated by abrupt and in some sense catastrophic transitions (Alley et al. 2003). Such events correspond to large, quantitative changes although in a high dimensional space it is important to note that such steps may not necessarily be large in all dimensions. Fig. 4 illustrates that many transitions in which one or the other environmental variable undergoes a very small change. This observation highlights the importance in identifying the significant axes of change in understanding high

Figure 6: Eq. (6) (left) shows the density of fixed points over a range of perturbations to be Gaussian distributed, such that exponentially fewer stable states are available in the face of large perturbations. Additionally we can derive the probability of a transition occurring in the increasing or decreasing  $P$ -direction as a function of  $P$  (right). While extrema are equally likely at any value of  $P$ , they are more likely to be maxima where  $P$  is negative, and minima where it is positive. Transitions encountered by increasing  $P$  are therefore more likely when  $P$  is positive and visa-versa. The width of the functions is related to the variance of  $F$ , which is normalised to  $\sigma_F^2 = 1$ .

dimensional transitions as opposed to examining a lower dimensional projection. It is also interesting to examine the probability that a transition occurs in the direction of increasing perturbation (local minima of  $F(E)$ ) or in the decreasing direction (local maxima). To achieve this, we examine the correlations between  $F$  and it's second derivative,  $F''$  by formulating the covariance matrix, the result of which is shown in Fig. 6. This illustrates that positive forcing is more likely to encounter a local minimum, and therefore a transition caused by increasing  $P$  while the reverse is true for negative forcing.

**Reversibility** The one-dimensional hysteresis metaphor describes a symmetrical loop, emphasising only that systems may be bistable over a range of external perturbation, and that sufficiently strong driving can move the system between states. However, while Fig. 5 shows such transitions exist, the two dimensional picture significantly obfuscates this as along with simple hysteresis loops, we see large numbers irreversible regime shifts. This occurs where driving in a particular environmental variable will not revert the system to its original state. This result would have particularly important consequences to real-world transitions. Transitions in lakes to eutrophic states for example reduce biodiversity and cause difficulty in water treatment (Wang et al. 2012). Reversing these transitions is a key concern, and this model emphasises the importance of a thorough understanding of the system in question. A system collapsed by strong driving in one dimension may not be recoverable simply by reversing the effect.

## Discussion

We have shown that self-regulation is a mechanism which may arise from a large population of random life elements, and explored this mechanism in a multi-dimensional environment. In particular, we note three important differences between the one-dimensional picture of hysteresis between bistable states; the magnitude of a regime-shift following a transition is highly variable, returning to a previous state after a transition may be impossible, and the density of viable states for a given perturbation is exponentially large with the number of environmental variables. These points prompt a number of questions when considering transitions in climatic or ecosystems; which aspects of the environment if any are expected to undergo catastrophic changes? Can the previous state be recovered, and if so, which are the important dimensions of control? How many alternative states are consistent with external forces, and therefore stable?

Two main questions are left open in our implementation. While it has been shown that the choice of function for the steady state populations about their niche is unimportant, a factor which would convolute this such as interspecies competition are not resolved. In this sense, we do not distinguish between the fundamental niche, the environmental conditions in which the species can survive and proliferate, and realized niche which is influenced by external factors such as interspecies competition and predation. While we mediate all biotic interactions through the environment, previous studies have concentrated on the individual species interactions, such as McDonald-Gibson et al. (2008) and Dyke et al. (2007) where increased interspecies competition appears to accentuate the homeostatic properties of a reign-control sys-

Figure 7: Shaded regions indicate the time taken for the system to recover from small perturbations from the fixed points of Fig. 5. The decay time is inversely proportional to the real part of the largest eigenvalue of the Jacobian evaluated at the fixed point. The discontinuity is caused by the transition between an over-damped system, where eigenvalues are real and perturbations decay exponentially, and an under-damped system where complex eigenvalues result in damped oscillations.

tem, despite other approaches which argue that increasingly connected systems lose stability (May 1972).

Also, the extent to which the separation of time scales between changes in the environment and biota are important to the model dynamics is unclear. While it has no influence on the model fixed points, illustrations of basins of attraction, such as Fig. 5 are expected to change significantly, and there is no clear way to represent them in a  $N + K$  dimensional system. However, some progress may be possible by assuming the simplest case of linear relaxation of populations towards some steady state value. Starting from Eq. (1), it can be shown that such a case removes the need to resolve the individual populations  $\alpha_i$ , reducing to a  $2N$  dimensional system. Multiplying by  $\omega_i$  and summing over the population gives

$$\tau_\alpha \sum_i \omega_i \frac{d\alpha_i(t)}{dt} = \sum_i \omega_i \alpha_i^*(\mathbf{E}, \boldsymbol{\mu}_i) - \sum_i \omega_i \alpha_i(t)$$

$$\tau_\alpha \frac{d\mathbf{F}(t)}{dt} = \mathbf{F}^*(\mathbf{E}) - \mathbf{F}(t) \quad (7)$$

by the definition for  $\mathbf{F}$  of Eq. (4). Previous work has shown that the relationship between the time scales of changes in the biota and changes in external perturbation set limits on the ability of a system to self-regulate, and invite a range of new phenomena to emerge (Weaver and Dyke 2012).

Critical slowing-down (CSD) (Lenton 2011) refers to the long relaxation time of near-critical systems, those which are approaching climatic or ecosystem transitions. As natural and anthropogenic pressures stress aspects of the Earth

system, it has been shown that certain time series find an increase in the auto-correlation coefficient precedes such transitions (Dakos et al. (2008) analyze eight ancient abrupt climate shifts). This signal suggests that the relaxation of the system towards its steady state slows as it approaches a regime shift. Fig. 7 illustrates the decay time of the system shown in Fig. 5 and verifies that the type of system described in this work exhibits this signal. The eigenvalues of the Jacobian in the vicinity of a fixed point yield information not only pertaining to the stability of the point, but also provide estimates of the decay time of small fluctuations from the fixed point. A large decay time indicates the system is in some sense *slow*. However it appears to possess no further information pertaining to the direction, magnitude or reversibility of the transition; clearly important and relevant questions when considering transitions in real systems.

## Abstract

The objective of this work is to better analyse and understand social self-organization in the context of social media and political activism. More specifically, we centre our analysis in the presence of fractal scaling in the form of  $1/f$  noise in different Twitter communication networks related to the Spanish 15M movement. We show how quantitative indexes of brown, white and pink noise correlate with qualitatively different forms of social coordination of protests: rigidly organized protests (brown noise), reactive-spontaneous protests (white noise) and complex genuinely self-organized protests (pink noise). In addition, pink noise processes present correlations that reach much further in time, maintaining a dynamical coherence that last several days, and also show a balance between mean distance and clustering coefficient within the interaction network.

## Introduction

Artificial Life models have helped identify processes of self-organization in the living domain, opening up our scientific imagination and improving our theoretical insight into complex phenomena, ranging from chemical autocatalysis (Kauffman, 1993) to emergent collective intelligence (Bonabeau et al., 1999; Holland and Melhuish, 1999). Human social *life* has also been approached through Artificial Life techniques and theoretical lenses (Hemelrijk and Kunz, 2003) but it is now, with the rise of social media and digital data-mining, that a new door is opened for a genuine analysis and synthesis of human social life (Lazer et al., 2009).

One of the central topics of Artificial Life modelling has been the emergence of spontaneous structures or self-organized processes in nature: how can a distributed process organize into a collective pattern that maintains some organizational invariance? how does complexity arise spontaneously without an organizing centre? under which structural and environmental or boundary conditions is that possible? One can pose these very same questions in the realm of social life. In fact our social life is often subsumed under emergent collective patterns. A particularly interesting domain to put these type of questions to practical use is the

realm of political organization and grassroots activism in social media. When is a process genuinely self-organized and participatory and when is it just an amplification of an organizing centre of power? Can “genuine” self-organization and the generation of a social “consciousness” be quantified?

The last years have witnessed an explosion of political activism based-on or catalysed-by social media. The Icelandic ‘Kitchenware Revolution’, Wikileaks ‘Cablegate’ and Anonymous’ network defence, the 2011 Arab Spring, the Spanish 15M movement, the Occupy Movement... are but a few among the many examples of the increasing role played by social media in grassroots political organizing. While these and similar social movements differ in many important ways, there is one thing they share in common: they are all interwoven through autonomous communication networks supported by the Internet and wireless communication (Castells, 2012). Social media has provided the tools for creating horizontal and interactive communication networks, boosting enormously the possibilities for self-organized political processes.

The objective of this work is to better analyse and understand social self-organizing processes in the context of social media political activism. More specifically, we centre our analysis in the presence of fractal scaling in the form of  $1/f$  noise in different activist communication processes related to the Spanish 15M movement. We will start describing the context of the Spanish 15M movement and providing a short introduction to the theoretical tools used for our analysis. Next we describe the data, measures and results of the study, and we finally discuss the consequences and limitations of our work.

## 15M Movement and Social Media Channelled Self-Organization

The presence of Internet and other digital media and the increasing use of multidirectional and interactive mass communication networks is starting to change radically the way societies organize themselves to constitute counter power or change power relationships with dominant institutions

(Castells, 2009). An important example of this phenomena is the protest movement that was born in Spain in May 15th 2011 (henceforth 15M movement). Initially, what would later become the 15M movement was organized via social media preparing a massive demonstration without much visibility in traditional media. Unexpectedly, this social media work triggered a huge social movement involving between 6.5 and 8 million people (El País, 2011) that has abruptly changed the political life in Spain. Together with other parallel experiences (like the Arab Springs, or the Occupy movement), the 15M has renewed the communication strategies of previous social movements, now seen as obsolete due to new communicative practices adopted by a large segment of the population (Toret, 2012). Frequently, activists involved with the movement have described its organizational practices as dramatically different to their previous political experiences. These statements suggest that the movement cannot be described just as a group of well-defined formal organizations confronting established institutions. Instead, they often take borrowed dynamicist and complex systems metaphors and describe the organized movement as a swarm or an autopoietic network, with distributed and emergent properties (Sanchez Cedillo, 2012), a system governed by organismic cycles in which the activity of the system is coordinated through powerful synergies (Malo and Pérez, 2012) or as a ‘self-organizing climate’ which envelopes society (Fernández-Savater, 2012).

Unlike previous studies of network analysis of the 15M movement and the similar uprisings, the focus of this paper is on characterizing more global aspects of self-organization processes and exploring indicators of the kind of emergent communication patterns. More specifically, we will focus on the constitution of the system as a coherent whole which can maintain a dynamic identity for a period of time. Since this type of self-organization into a coherent dynamic unit is hypothesized to be the core of mental life and neural organization (Van Orden et al., 2003), we want to explore the possible analogy with social life and political consciousness.

### Fractal Scaling and Self-Organization in complex networks

One of the greatest challenges for the understanding of cognitive and social system is finding formalisms to understand how complex activity emerges from processes of multi-scale organization. During the last decade, different authors have proposed methods of fractal analysis as a solid candidate for this task (Dixon et al., 2012).

Fractal scaling is characteristic of critically self-organized systems (Bak et al., 1987). In these systems we can find an interesting mix between stability and instability creating complex structures of the variability of the system’s activity. Thus, processes with fractal scaling present a constant relation between the size of their fluctuations and the scale in which they occur: systematically larger fluctuations for

longer scales and smaller fluctuations for shorter scales. We often describe fractality in a process through its spectral density function  $S(f)$ , which in the case of fractal scaling exhibits the form:

$$S(f) \propto f^{-\beta}$$

where  $f$  stands for the different frequencies in which the activity of the process takes place, and  $\beta$  defines a log-linear relationship between the spectral power content at different scales of  $f$ . The presence of log-linear relationships in the spectral density suggests that the activity of the system is self-organized into a nested temporal structure, in which the different rates of activity of the components of the system are coupled into a coherent macroscopic whole. More specifically,  $\beta$  shows what is the relative influence of each scale in the system. Different values of  $\beta$  describe different relationships between the weight of fast, medium, and slow timescales in the composition of a self-organized system.

The analysis of the fractal coefficients of a system’s activity has been widely used in neuropsychology for characterizing different states of interactivity among the component of a cognitive system, as well as to predict the emergence of new cognitive structures (Dixon et al., 2012).

More concretely, different values of the  $\beta$  parameter allows us to characterize different types of processes:

- White noise ( $\beta = 0$ ) describes fully random fluctuations with no correlations in time (processes with no memory). White noise processes show a strong dependence on short time scale events (scales with higher frequencies). White noise processes display fast changes in their activity but are unable to maintain structured and coherent patterns.
- Brown noise ( $\beta = 2$ ) resembles a diffusion process with no correlation between increments, but with a strong dependencies between the position of one sample and the next, presenting a “memory” of previous events. It shows a strong dependence on long time events, where small frequencies give a much greater contribution to the noise structure than the rest. Brown noise processes are able to maintain stable structural patterns, but they are unable to flexibly modify their activity when fast changes are required.
- Pink noise ( $\beta = 1$ ) describes processes in which an equilibrium is found between the influence of short, medium, and long timescales. It finds an equilibrium between disordered states with high informational content (white noise) and states with strong memory but low informational content (brown noise). Pink noise processes display dynamics which can maintain stable patterns of activity while being able to flexibly regulate their level of activity.

Fractal behavior has been frequently found in biology, psychology and neuroscience during the last decade, and

fractal analysis have been used for characterizing the underlying structure of system producing complex behaviour. In psychology, fractal coefficients have been successfully used for the better understanding of different types of atypical developmental conditions and the prediction of cognitive outcomes (Dixon et al., 2012). Also, deviations from  $\beta = 1$  fractal scaling, either toward white or brown noise, have been found in different health conditions as epilepsy (Ramon et al., 2008), heart failure (Goldberger, 2002), developmental dyslexia (Wijnants et al., 2012b), among many other examples (Wijnants et al., 2012a).

Although there is still controversy about the meaning of fractal scaling and its origin (Van Orden et al., 2005; Diniz et al., 2011), one position in the debate is that fractal scaling is a characteristic manifestation of self-organizing systems, which reflects the balance between independent and interdependent activity of their components. In this sense, deviations from perfect  $\beta = 1$  pink noise would imply unbalancing this equilibrium in favour of either independent or interdependent activity, affecting the ability of a system to behave in a self-organized manner. Recent years have witnessed increasing empirical support for the idea that pink noise may result from the interaction of many ongoing processes over a multiplicity of interdependent scales (Kello et al., 2007; Dotov et al., 2010; Wijnants et al., 2009).

According to these ideas, the measured  $\beta$  coefficient can account for the type of underlying structures of complex phenomena. The absence of long-range correlations when  $\beta = 0$  implies that the different processes composing the system are highly independent, provoking uncorrelated randomness in the systems activity. This describes a situation where the ongoing activity is not self-organized at all and there is not a coherent collective pattern emerging from their activity. On the other hand we have  $\beta = 2$  processes where slow timescales dominate over others. These systems will display highly predictable patterns which will strongly constrain the individual dynamics of the system components, strangling the self-organization in favour of rigid and inflexible collective dynamics. Finally, when  $\beta = 1$ , slow and fast timescales are compensated, and the influence of independent and interdependent activity is perfectly balanced; the activity of the system is going to depend on the ongoing reciprocal interactions between timescales, finding an equilibrium between stability and spontaneity. As a result  $\beta = 1$  becomes an indicator of distributed self-organization in a coherent whole: different parts of the system (with their characteristic frequencies) appear globally coordinated in a reciprocally influencing manner.

## Methods

Now that we have proposed an indicator for characterizing different self-organization processes, we wish to apply it to answer questions about different instances of grassroots political mobilization. What is the relationship between indi-

vidual political activity and the collective global process? Are processes of political organization of the digital age spontaneous angry mobs or just mindless followers of popular topics? What is the degree of collective 'political consciousness' in social media-based mobilizations?

We now proceed to present different sets of data about a series of political events that we have classified according to qualitative experience from observation and a set some measures aiming to provide quantitative indicators for answering some of the questions above.

## Data and qualitative analysis

We have collected Twitter data from different protests taking place during May 2012, one year after the start of the 15M movement. That month was chosen because of the high density of mobilizations, allowing us to compare different organizational processes taking place in the same short period (thus neutralizing the influence of contextual factors and differences due to large scale variations on composition and methods of the 15M movement through its historical evolution). We downloaded around 385,000 Twitter messages using 20 different *hashtags* (labels used in twitter to identify conversational topics). Following the advice of activists involved within the protests, hashtags were chosen as representative of different types of processes for mobilization and protest:

- Events related to an education strike taking place on May 22 (#22M, #HuelgaDeClase), which follows a more traditional pattern of organization, with unions and other centralized organizations leading protesters, a fixed schedule of pickets, events, demonstrations, and a more predictable process of escalation of the mobilization as the strike date approaches.
- A series of events coinciding with the anniversary of the start of the 15M movement (with the global label #12M15M), from May 12 to May 15, consisting mainly on a series of previously planned demonstrations named through different labels (#ALaPlaza12M, #Es15M, #YoVoy12M, #Feliz15M). Some of these pre-planned events evolved into a series of spontaneous and more creative actions, as a campaign against the Bank 'La Caixa' (#LaCaixaEsMordor) that spontaneously turned into a camp in front of the Headquarters of La Caixa with daily casserole protests under the label (#OccupyMordor).
- Some events correspond to planned actions or proposals launched by some participants of the movement and amplified by the rest of the network in a distributed and decentralized way. This has been a characteristic mode of functioning of the 15M movement, which avoids formal leadership and centralized organization in favour of a more diffuse organization exploiting the possibilities of social media. Some examples of this

are #PlandeRescateCiudadano, #BankiaEsNuestra, #15MSectorRadical, #NurembergFinanciero or #CierraBankia.

- One special case of the category above is the case of #15MPaRato. A team of activists and lawyers launched a campaign aiming to file a lawsuit demanding that the former director of *Bankia* (an Spanish bank accused of being a major responsible for the Spanish financial crisis), Rodrigo Rato and the rest of the director's board, be held accountable for mismanagement and possible criminal behaviour. The campaign was cooperatively designed to synchronously seed the message through a group of well positioned nodes within the movement's network, aiming to work as "catalysts" to create a supporting community for the organization of a *citizen's lawsuit*. This strategy turned out to be very successful, the hashtag #15MPaRato quickly became trending topic in Spain and it reached the first position between the global trending topics soon after, it also managed to collect € 15000 of funding in less than 24h and contacting with tens of Bankia's stockholders and employees willing to take part as witnesses for the trial.
- A last set of events correspond to fast and spontaneous reactions to unexpected incidents, such as the moment where the Spanish risk premium reached the symbolic value of 500 points (#Prima500), the police eviction of a social centre that was central to the movement (#LaRimaia), the eviction of the protesters camped in Sol square in Madrid during the #12M15M protests (#DesalojoSol), or the spontaneous demonstration that followed as reaction to this last eviction targeting Madrid's Stock Exchange Building (#ALaBolsa).

The task is now to test whether fractal scaling analysis can provide a good *quantitative* index for these *qualitatively* different degrees of self organization of social communication and coordination expressed through Twitter.

### Detrended Fluctuation Analysis

The detrended fluctuation analysis (DFA; Peng et al., 2000) is a method for determining the statistical self-affinity of a signal. In a nutshell, the DFA algorithm integrates the analysed time series and then divides it into boxes of equal length  $n$ . For each box and each value of  $n$ , a least squares line (the trend of the signal within that box) is fit to the data. For each box size  $n$ , the characteristic size of the fluctuation  $F(n)$  is computed as the rms deviation between the integrated signal and its trend in each box. This computation is repeated for every value of  $n$ . Typically,  $F(n)$  increases with  $n$ . A linear relationship on a log-log plot with slope  $\alpha$  indicates the presence of fractal scaling in the analysed signal (Figure 1). Where  $\alpha$  is an approximation of the Hurst exponent, and is related to the scaling in the Power Spectrum of the Fourier analysis being  $\beta = 2 \cdot \alpha - 1$ .

Figure 1: Detrended fluctuation analysis of the time series of tweets with the hashtag #22M. The squares represent the values of  $F(n)$  for each value of  $n$ .  $C_L$  is the larger value of  $n$  where the linear correlation still holds. The solid line represents the linear approximation of the 30 first samples under  $C_L$ .  $\alpha$  represents the slope of the linear fit and  $\beta$  its corresponding value of fractal scaling in the frequency spectrum. Copyright 2013 Miguel Aguilera Creative Commons Attribution-ShareAlike 3.0 Unported License

their common fractal dimension  $FD$ , which for spectral analysis takes the form  $FD = 0.1\beta^2 + 0.4\beta + 1.5$ , and for DFA  $FD = 0.4\alpha^2 - 1.2\alpha + 2$ .

For each hashtag, we created a time series composed of the number of messages that were written using that label at each instant of time (with a sampling period of 1s). The DFA algorithm was applied to the resulting series, obtaining the  $F(n)$  values for each box size  $n$ . After that, we identified the larger value of  $n$  where the shape of  $F(n)$  started to have a log-linear relationship. This value, which we will define as the correlation length of the process ( $C_L$ ) (Figure 1), represents what is the larger scale where the fractal scaling holds. Over larger scales, the fractal relationships break down. We interpret this value as an indicator of how long a process can exist as a self-organized entity. Even if the process exists (i.e. the hashtag is used) for a longer time period, the emergence of coherent patterns of behaviour will not be larger than the value of  $C_L$ . Once identified, this temporal boundary of the self-organized process, we proceed to compute the fractal relations for smaller values of  $n$ . In order to avoid artefacts for small values of  $n$ , potentially due to the chosen sample rate (see Wijnants et al., 2013), we computed the value of  $\alpha$  by fitting a least squares line of the 30 samples from  $C_L - 29$  to  $C_L$  (Figure 1). The obtained trend was transformed into its corresponding value of  $\beta$ .

### Network Analysis

After analysing the scale invariance of the different processes, we have completed our study by analysing the un-

derlying networks generating those dynamics. We have taken the set of interactions between Twitter users (mentions, replies, retweets) using each of the hashtags to create a directed graph where each user is a node and interactions are represented by weighted edges. This graph represents the structure of interactions behind the communicational processes of each hashtag. For each network we have measured the following parameters and properties:

**Degree of a node** The degree of a node  $k_i$  represents the number of incoming and outgoing connections of that node.

**Clustering Coefficient** It measures the connection density among the direct neighbours of a node. If we define  $M_i$  as the number of connections between the neighbours of a node  $i$  we can compute the mean clustering coefficient of a network with  $N$  nodes as:

$$C = \frac{1}{N} \sum_{i=1}^N \frac{M_i}{k_i(k_i - 1)}$$

A high Clustering coefficient implies a robust structure of the network.

**Mean distance** Distance  $d(i, j)$  in a network measures the shortest path between two nodes  $i$  and  $j$ . The mean distance of a network with  $N$  nodes is computed as:

$$L = \frac{1}{N(N-1)} \sum_{i,j} d(i, j)$$

**Small World Networks** Small-world networks are defined as networks with high clustering coefficient and low mean distance (Watts and Strogatz, 1998). These networks have interesting properties which allow to easily find the shortest path between two nodes. Communication processes over small world structures will be much more robust and efficient. We can know if a network has small world properties from its clustering coefficient and its mean distance. Since the clustering coefficient and mean distance are strongly influenced by the size of the network, we have normalized both  $C$  and  $L$  by dividing them by the clustering coefficient and mean distance of a Erdős-Rényi random network with the same size and edge density  $C_r$  and  $L_r$ . A network will have small world properties when  $C_L \gg 1$  and  $L_r \sim 1$ .

**Scale-Free Networks** Small-world networks in nature often are found in the form of scale-free networks. Scale-free networks (Barabási and Bonabeau, 2003) can naturally grow by preferential attachment of its nodes, resulting in networks in which some nodes called ‘hubs’ have a very high connectivity while the majority of the other nodes are poorly connected. Scale-free networks are characterized by a power law in its distribution of node degrees.

$$P(k) \sim c \cdot k^{-\gamma}$$

where  $k$  and  $\gamma$  are constants. All the networks analysed in this work displayed power law distributions of their degree distribution. Thus, we have computed the values of  $\gamma$  for both the incoming and outgoing degree of connections using a linear regression on the logarithmic distribution of  $P(k)$ , obtaining two coefficients  $\gamma_{in}$  and  $\gamma_{out}$  for each network. The  $\gamma_{in}$  coefficient will represent the inequality in how the nodes act as sources of information. A high value of  $\gamma_{in}$  will imply that a few nodes are generating most of the information travelling through the network. In turn,  $\gamma_{out}$  will represent the inequality in how the nodes propagate this information. A high value of  $\gamma_{out}$  will mean that only a few nodes act as amplifiers of information in the network.

## Results

Following the methods above, we have analysed the fractal exponent and the network properties for the 20 hashtags described above.

### Fractal Scaling

In figure 2 we present the obtained values of  $\beta$  and  $C_L$ . As we can see, the values of  $\beta$  range between pink and brown noise (between 0 and 2), with some values very close to pink noise ( $\beta = 1$ ). The results of  $C_L$  also present quite different results, displaying more than two orders of magnitude between the shortest and larger temporal scope of the self-organized coordination.

In a closer inspection of the results, we can observe how different types of mobilization processes can be identified with different values of  $\beta$ . For example, the more rigidly organized process of the education strike (#22M, #HuelgaDeClase) displays values of  $\beta$  closer to the smoother dynamics of brown noise. On the other hand, most of the “spontaneous” processes (#ALaBolsa, #LaRimaia, #DesalojoSol), together with some of the messages amplified by the network (#15MSectorRadical, #NurembergFinanciero, #LaCaixaEsMordor, #BankiaEsNuestra). Finally, some processes seem to achieve an equilibrium between independent and interdependent dynamics and are quite close to pink noise (#15MpaRato, #12M15M and some of its related hashtags, #PlandeRescateCiudadano, #16M, #Prima500, #OccupyMordor), suggesting that these processes reach some middle point between the spontaneousness of white noise and the stability of brown noise.

Figure 2 also shows a correlation between the values of  $\beta$  and  $C_L$ . We have fitted the obtained values of  $\beta$  and  $C_L$  with a rational polynomial function of order two for both the numerator and denominator. The quality of the fit was measured by a  $R^2$  coefficient of 0.69. We observe how values of  $\beta$  closer to one display much higher values of  $C_L$ , suggesting that when the process of self-organization reaches a dynamic equilibrium between independent and interdependent dynamics it spans into much larger temporal timescales.

That is, independently of the real duration of the communication process, pink noise processes present correlations that reach much further in time, maintaining a dynamical coherence that lasts up to days in the cases with highest values of  $C_L$ .

### Network Properties

Once the different types of self-organization processes have been classified according to their fractal exponents, we proceed to compare these results with the properties of their underlying networks.

**Small-World Properties** We have approximated the least squares second order curve of the normalized clustering coefficients and mean distances in relation to the obtained fractal coefficients  $\beta$  (Figure 3). The results show that different types dynamics are related to different types of underlying network structures:

- White noise (low  $\beta$ ): these processes have low values of  $C/C_r$  and  $L/L_r$ , which means that their underlying networks have lower clustering coefficients (less robust structure) and shorter mean distances (faster information transfer). These results coincide with the idea of white noise processes as being spontaneous and viral but poorly organized processes which disintegrate quickly. Low clustering values and short distances also suggest that independent activity of the nodes has a higher influence on the dynamics of the system, since the activity of individual nodes travels fast and there is not a robust structure of stable communities.
- Brown noise (high  $\beta$ ): these processes in turn present higher values of  $C/C_r$  and  $L/L_r$ , meaning that their underlying networks are robust and well structured but have long communication paths. This is also compatible with the idea of brown noise processes being more robust but less flexible. A high clustering coefficient and long mean distance also suggests a bigger influence of interdependent activity, since communities are strong and the transmission of information through the network is slow.
- Pink noise ( $\beta \sim 1$ ): these processes find an equilibrium in which they have quite high values of  $C/C_r$  and not very long mean distances  $L/L_r$ . Again, pink noise processes manage to have the best from white and brown noise processes, being robust at the same time as they are fast in the propagation of information.

**Scale-Free properties** We have approximated the least squares second order curve of the scale-free  $\gamma_{in}$  and  $\gamma_{out}$  coefficients in relation to  $\beta$  (Figure 4). We observe how there is a dependence between  $\gamma_{in}$  and  $\beta$ , finding that white noise processes present a more egalitarian distribution between the nodes that generate the contents of the communication,

while in brown noise processes there are fewer nodes leading the communication process. In the case of  $\gamma_{out}$  it does not seem to have any strong correlation with  $\beta$ , suggesting that the role of the nodes as diffusers of the information is the same independently of the type of the self-organization process going on.

### Discussion

In previous sections we have presented fractal analysis as a candidate for quantifying and identifying different types of social coordination in communication networks. Concretely, we have proposed fractal scaling in the frequency spectrum of the activity of a connected crowd as an indicator of how it constitutes itself as a collective social system through ongoing interaction. We have measured fractal scaling as the relation between the amount of variability of the system

Figure 2: Values obtained for  $\beta$  and  $C_L$  (the latter measured in seconds) for the time series of messages with each hashtag. The solid line represents a rational polynomial fitting of the displayed values. Copyright 2013 Miguel Aguilera Creative Commons Attribution-ShareAlike 3.0 Unported License

at different temporal scales, obtaining a parameter  $\beta$  that describes the fractal relations between the amount of activity in the system at different temporal scales. We have also measured other parameters like the temporal scope of the fractal scaling and properties of the network underlying the communicative activity.

Results have shown how processes which equilibrate the influence of the different temporal scales of activity (those with  $\beta = 1$ ) display properties that suggest that the ongoing process of self-organization is stronger than in other cases, as a larger fractal correlation length  $C_L$  or more marked small world properties. In addition, the processes with  $\beta \sim 1$  coincide with those social mobilizations having a mix of planned or stable development with more spontaneous or surprising turnarounds.

In contrast, processes with an unbalanced dynamical scaling, favouring either short-scale activity or long scale activity, do not display desirable properties for collective self-organization. The larger presence of fast or slow timescales implies that the system is giving preference to either independent or interdependent activity over the other. For example, we have seen how spontaneous reactions of social media activists to unexpected events tend to show white noise scaling, suggesting that the system is not really self-organized into a coherent unit of activity, but is rather the sum of the activities of a uncoordinated crowd reactively triggered by an external stimulus. On the other hand, we have seen how processes organized according to more rigid schemes, like as a strike, tend to brown noise scaling, suggesting that interdependent activity dominates the dynamics of the process, leaving no room for true self-organization as the individual dynamics are enslaved by the collective communicational process.

Despite the consistency of the present results, fractal scaling analysis must be taken carefully. Although fractal scaling is usually taken to emerge as a result of a self-organized processes, there is evidence suggesting that this is not always the case, and there are cases where fractal scaling can be the product of linear combinations processes without fractal scaling (e.g. with a linear superposition of random components acting on multiple time scales, see Hausdorff and Peng, 1996). To avoid this problem, some authors have suggested multifractal analysis to ensure the nonlinear nature of the ongoing interactions that build the self-organized process (Ihlen and Vereijken, 2010). In an extension of the present work (to be published) we have analysed the multifractal structure of some of the data presented here, confirming the relation between pink noise exponents and non-linear self-organized interactions we have claimed here.

Further progress in this direction might demand a more synthetic approach to test how artificial network topologies and communication dynamics yield different forms of noise and correlation length. Artificial Life techniques, like genetic algorithms, could be helpful to find optimal communication strategies in order to build genuine self-organized processes, including parametric analysis of the effect of variables such as degree of consensus, viral potential, external mass-media coverage, etc. Fractal scaling indexes could be used as fitness functions for these models.

## Conclusion

The generalization of social media in everyday communication is a game changer for the analysis and understanding of self-organization in our social and political life. On the one hand, the use of digital communication networks has allowed to overcome some important limitations and diffi-

culties for organizing large scale groups of people without a hierarchical structure (the series of political uprisings we have witnessed in the last 3 years is a good indicator of this potential). On the other hand, social media allows us to easily collect data from social interactions in different contexts. What is still missing is a deeper understanding of how social media network topology and dynamics correlates with different forms of collective action and self-organized coordination.

We have performed an analysis and comparison of 20 different communicative processes related to grassroots political mobilizations within the Spanish 15M movement in May 2012. A qualitative classification of these processes was shown to match the quantitative measurement of fractal scaling analysis of the message exchange time series. A balance between fast and slow temporal scales, described by a *pink noise distribution*, seems to boost the robustness and the life-span of genuine self-organized processes. Pink noise processes in social networks were also shown to be closely related with the stronger small-world properties of their underlying networks. Further analysis and modelling of social and political self-organization is required to support the hypothesis advanced in this paper but we might be witnessing the emergence of a pink noise revolution where it is the dynamics of social interaction (rather than the specific content being communicated) what matters. To say it paraphrasing Marshall McLuhan's celebrated motto, we might have entered an era where *the noise is the message*. And a science of Artificial (social) Life is perfectly suited to push this message forward.

# Biology of Digital Organisms: How Language and Tools Construct Reality

Orly (Kramash) Stettiner<sup>1</sup>

<sup>1</sup>Program in Science, Technology & Society (STS), Bar-Ilan University, Israel  
orlyst@netvision.net.il

## Abstract

When Christopher Langton first coined the term "artificial life" and organized the first conference of the nascent field in 1989, he envisioned that "We would like to build models that are so life-like that they cease to become models of life and become examples of life themselves." (Langton 1989). When Thomas Ray referred to his Tierra creatures four years later, he said: "These are not models of life, but independent instances of life" (Ray 1993).

Katherine Hayles, the American postmodern literary critic was startled by this vision and wondered how it was possible, in the late twentieth century, to "believe, or at least claim to believe, that computer codes are alive? And not only alive, but natural?" (Hayles 1996). The American philosopher of science Evelyn Fox Keller supported Hayles's view and generalized it into the linguistic domain (Keller 2002).

In this paper we briefly describe Hayles and Fox-Keller's claims, which will follow by an extended examination of how the usage of language, visualization and analysis tools have continued to construct and shape the field of ALife in the decade since their articles were published. Through this inspection, we suggest that the extensive usage of biological terminology and tools may give researchers a false impression regarding the validity and scientific significance of the experiments involving artificial simulated "organisms".

## Introduction

### Hayles's Narratives

Katherine Hayles concentrated on stories told about, and through, the evolving computer programs, where she identifies two levels of narratives, multilayered systems of metaphors: The textual-visual level and the strategic level.

The first level refers to the textual and visual representations of the environments, in which the artificial creatures develop. "In these representations", she said, "authorial intention, anthropomorphic interpretation, and the program's operations are so interwoven that it is impossible to separate them". Biomorphing naming such as "birth/death", "mother/daughter cell", "ancestor", "parasite", and their redefined interpretations reveal an intention of enabling a dynamic emergence of evolutionary processes within the computerized environment. The visual depiction of the code, in the form of sequenced images, imposes a feeling of real existence of living creatures within the computer. Ignoring the fact that the code is actually the organism and vice versa, the "creatures" gain a phenotypic

expression, a "body"- both visually (through specific shape, size and color) and verbally.

The Strategic level includes arguments and "political" strategies, used to position ALife as a research field within Theoretical Biology. New possible forms of "life-as-it-could-be" emerge spontaneously and evolve within the computer. Such attempts to synthesize life-like behaviors from simple rules and building blocks are claimed to complement the traditional analytic biological sciences that deal with "life-as-we-know-it". The essence of life, narrowed into complex logical forms, is claimed to be independent of medium. Thus, the ALife programs, considered alive themselves, are worth of studying as alternative evolutionary silicon-based pathways, which becomes a model for understanding the natural processes.

These narratives, as Hayles claimed, translate the operations of computer codes into dramatic biological analogues of a Darwinian struggle for survival and reproduction, the rise and fall of races, invented strategies for effective evolution, cooperation and competition.

### Fox Keller's Lexicon

The American philosopher of science Evelyn Fox Keller supported Hayles's view, emphasizing the linguistic domain. Referring to the extensive biological lexicon, which ALife researchers developed for interpreting their models, she wrote, "it adds substantively to the sense of proximity to the real-life examples for which they aim" (Keller 2002, p. 277). Much like Hayles' note that "the organism is the code and the code is the organism", Fox Keller emphasized a persistent ambiguity and even identity of the words "genome", "program" and "body" of digital organisms, as a central agenda.

Fox Keller emphasized the increasingly narrowing and illusory gap between computers and organisms, as reflected by the terms "computational biology" and "biological computation", wondering if this convergence (both material and conceptual) can lead to an indistinguishable gap between the living and non-living. In her analysis, Fox Keller makes two major statements, regarding the achievements, in her view, of ALife simulations at the time of writing (2002).

(1) "The failure (at least to date) to generate the kinds of complex mechanisms observed in biological evolution weakens the claim of such models to enhance our understanding of life-as-we-know-it" (p. 281).

(2) "The models of A-Lifers have thus far failed to engage much interest among their biological colleagues" (p. 283).

At the end of this paper we shall examine the current validity of these two statements.

Over a decade has passed since the prognosis of Hayles and Fox-Keller. The discipline of Artificial Life and digital evolving organisms has become a mainstream, almost fully accepted and established field of research, at least as a method of studying evolution, with its own conferences and publications.

An investigation into some of the leading research reports in this field shows that the narrow trail, which Hayles and Fox Keller identified a decade ago, was followed by others and broadened into an actual highway. To demonstrate this trend we selected to focus on three levels, which we identify as central to the process: The linguistic level, the methodologies and analysis tools level and the human factor.

### The Linguistic Level

At the linguistic level, we join and reinforce Hayles and Fox Keller, through the detection of an extensive and seemingly deliberate massive usage of re-defined biological concepts and anthropomorphisms of digital organisms, creating a vocabulary that becomes the mainstream convention.

The famous Swiss linguist Ferdinand de Saussure (1857-1913), the chief forerunner of structural linguistics, defined language as a collective product of social interactions. A meaning of a word is determined through differences, relative to other words or concepts. These differences structure our perception, and thus- language constructs our perceived reality. Therefore, naming digital objects after salient biological ones (like genotype or mutation) automatically categorizes them in the biological sphere.

During the 1930's, it was the American linguistic Benjamin-Lee Whorf, who advocated the idea that the structure of a language affects the way in which its speakers perceive and conceptualize their world and even their cognitive processes.

In the 1970's, philosophers and other scholars recognized the importance of language as a structuring agent, in what is known as 'the linguistic turn'. This turn began with the post-structuralism movement that followed De-Saussure and included influential theorists, such as Michel Foucault and Jacques Derrida. Language turned from being a tool for communicating messages into the message itself. Through daily usage of language we constitute our reality in an ongoing process of construction, modification and redefinition.

Genetic Algorithms became popular within computer science, with the early studies of Cellular Automata by John Holland (1975). Genetic Algorithms- by their very name and biological origin- naturally used terms adopted from Genetics: A population of randomly generated strings (called chromosomes) constitutes the genotype (or the genome), which encode candidate solutions (called individuals or phenotypes) to an optimization problem. In each generation, the fitness of every individual is evaluated, which serves as a basis for stochastic selection and modification (through recombination and possible random mutations) to form a new evolved population.

During the last decade, this preliminary basic lexicon was warmly adopted and widely extended to describe the digital

organisms, which live and evolve within machines, such as Avida.

The "Avidians", as the citizens of Avida are affectionately called, "can send messages to each other, produce and consume resources, and sense and change their environment's properties". They might be required to "communicate with neighboring organisms" (McKinley, Cheng et al. 2008). They "consume resources and generate by-products that can themselves serve as resources for other individuals" (Yedid, Ofria et al. 2008).

These descriptions and others attribute to these creatures traits and capabilities usually attributed to living creatures, specifically the ability to choose and to make knowledgeable independent decisions. This, in addition to the recurring statement that "Avida does not simulate evolution- it is an instance of evolution" (Pennock 2007), seems like a persistent attempt to designate the digital organisms a status of being an "instance of life" or even "an instance of an intelligent life".

Figure 1: Schematic demonstration of language usage by digital organisms' researchers.

The basic vocabulary created for the original Genetic Algorithms has since expanded vastly to include every aspect of the biological research. It's not just organisms and population, genotype and phenotype, crossover and mutations, birth and death. It now also involves the Metabolism and Metabolic Pathways, Adaptation, Genetic drift and Fixation, Implicit and Explicit mutations, Sexual and a-sexual reproduction, single and multiple niche worlds, and even synergistic and antagonistic Epistasis.

Looking back over three decades ago, one might recall a brilliant critic paper written by an AI researcher, Drew McDermott, who attempted to ridicule some of the common Artificial Intelligence conceptual and linguistics trends, which he calls "mistakes" (McDermott 1976). One such trend was the use of wishful mnemonics: identifiers of programs or data structures named after grand concepts such as "Understand", "Resolve", "Think" or "Associate", describing their desired purpose but not their actual functionality. Referring to the "Is

a..." relation, which is commonly used by AI programmers, McDermott writes:

"Concepts borrowed from human language must shake off a lot of surface-structure dust before they become clear. 'Is' is a complicated word, syntactically obscure. We use it with great facility, but we don't understand it well enough to appeal to it for clarification of anything. If we want to call attention to the 'property inheritance' use, why not just say *INHERITS-INDICATORS*? Then, if we wish, we can prove from a completed system that this captures a large part of what 'is a' means....

People reason circularly about concepts like 'is a'. Even if originally they were fully aware they were just naming *INHERITS-INDICATORS* with a short, friendly mnemonic, they later use the mnemonic to conclude things about 'is a'." (McDermott 1976).

A similar adoption of concepts and naming occurs within ALife, which partly evolved as a separate field in AI, only here the concepts are not borrowed from natural language but rather from Biology. Having recognized the importance of language as a tool for reality construction, we find this usage of biological vocabulary a result of a deliberate affiliation and self-identification on the part of ALife researchers with the discipline of biology, rather than that of computer science. The selected language is becoming a message, it constitutes a modified reality, in which all organisms are alike, the living and the digital, all go through the same evolutionary processes, all become alive, reproduce and finally die, all struggle for survival, where the fittest has the best chances, all compete and sometimes collaborate, they are all actually the same.

## Methodologies, Assessment and Analysis tools

A most fascinating aspect we identified in the process of adopting ALife into mainstream biology is the extensive usage of methodologies, assessment and analysis tools, widely adopted by A-Lifers from molecular biology, evolutionary biology and bioinformatics. We hereby demonstrate five of these tools:

(1) **Fitness Landscapes or Adaptive Landscapes** are concepts created in evolutionary biology, first introduced by Sewall Wright in 1932, to visualize the relationship between genotypes (or phenotypes) and their reproductive success, which is referred to as the "fitness" and visualized by the height at each point of the landscape.

Figure 2: Fitness landscapes of living organisms, right (Elena and Lenski 2003) and of digital organisms, left (Hazen, Griffin et al. 2007)

The concept has gained importance in evolutionary optimization problems, followed by its adoption for describing the fitness function of digital organisms.

In Fig. 2, hypothetical fitness spaces are sketched (on the right) to describe the dynamics of evolutionary adaptation of bacteria and viruses (Elena and Lenski, 2003), while on the left, the fitness function space is shown, describing four classes of possible sequence solutions for digital populations evolving on Avida (Hazen et al., 2007).

(2) **Phylogenetics** is the study of evolutionary relations among biological species or populations, which is usually discovered through molecular sequencing and morphological data. Phylogenetic depth refers to the cumulative number of generations or lineages by which organisms differ from their common ancestor. A usage of this tool was presented, for example, in *Evolutionary Biology* magazine for the analysis of a large protein database, and in *"Systematic Biology"* journal to show the speciation of two groups of beetles

Figure 3: Phylogenetics analysis of digital organisms as presented by (Lenski et al, 2003) on the right and (Chow et al. 2004) on the left.

(*Aphanarthrum* and *Coleobothrus*).

Researchers of digital organisms adopted the concept and tool to present phylogenetic depth analysis, based on the number of generations in which an organism's genotype differs from its parents, where the colors indicate the relative abundance of genotypes at a specific depth (Lenski et al, 2003), (Chow et al. 2004).

(3) **Gene Expression Profiling Analysis** – also known as Functional Genomics Array, is a strategy developed by molecular biologists to describe genes functions and interactions. The profiling can present the measurement of the activity (expression) of thousands of genes at once, to create a global picture of cellular functionality under specific conditions. Each column usually represents a specific

experimental condition, whereas each row stands for a particular gene. A color-coded scale is used, where red generally represents expression greater than a certain reference, green is less than that reference, and gray or white is missing or excluded data (for example, Fig. 4A from (Glaser 2011), Fig. 4B from (Shoemaker et al. 2001).

Figure 4: Gene expression profiling as used for living organisms: (a) by (Glaser 2011), (b) by (Shoemaker et al. 2001) and for digital organisms (c) by (Adami 2006).

The strategy was adopted by ALife researchers (e.g. (Adami 2006), as shown in Fig. 4C) to show the effect of knocking out individual computational instructions on the functions (which are actually the Genes) of a digital organism. The color codes look familiar: white indicates an unaffected function, red signifies a turned off (not expressed) function, whereas green signals functions that are turned on (the gene is expressed).

The overall resemblance between the original and adopted tool is remarkable and seems to be deliberate.

(4) **Sequence Alignment** is widely used in bioinformatics to arrange sequences of DNA or RNA (composed of nucleotides) or proteins (composed of amino acids), to identify regions of similarity, reflecting conserved regions, a consequence of functional, structural or evolutionary relationships between the sequences (e.g. (Brachner et al., 2012) (Karpinets et al., 2010), Fig.5A, 5B).

Researchers of digital organisms adopted this technique (Fig.5C, Adami 2000), to visually present the genome sequences of an entire Avida population, existing at a specific generation. The sequencing results demonstrate- at each genome site- the level of entropy, meaning- how variable or conserved this site is. Red sites are highly variable, whereas blue sites are conserved (having low entropy), as can be expected from the common practice in genomic sequencing of living organisms.

(5) **Gel Electrophoresis** is a well known procedure used in molecular biology to separate and sort a mixed population of DNA and RNA fragments by length, or proteins by electric charge, when they are made to move through a gel, usually made of PolyAcrylamide. DNA may be visualized using Ethidium Bromide which, when intercalated into DNA, fluoresce under ultraviolet light.

Recently, an attempt to sort and recognize digital viruses (referred to as "malware" or "cyber organisms") were made, using the same adopted procedure (Jaenisch 2010). The digital viruses, considered to be a collection of polypeptides, forming information-bearing protein structures, were analyzed using a mathematical analog to the 2-Dimensional PolyAcrylamide gel electrophoresis process, where again- the colors and general appearance seem familiar (Fig. 6).

These examples of methodologies and analysis tools, which originated in mainstream fields (such as molecular or

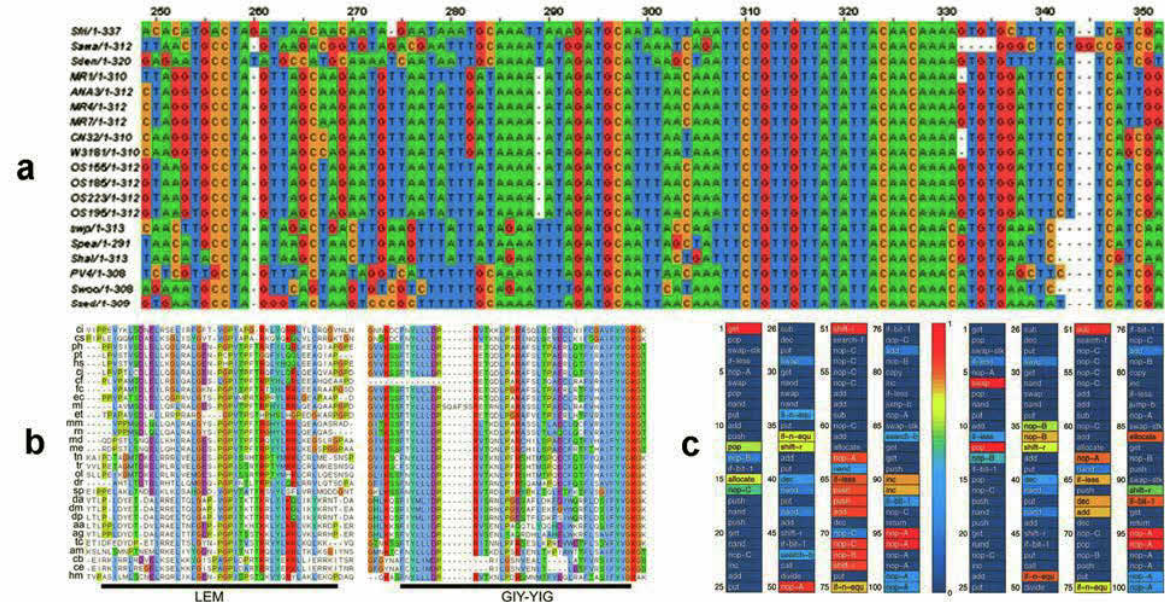

Figure 5: Examples of sequence alignments used for living organisms ((a) From (Karpinets et al., 2010), (b) From (Brachner et al., 2012)), and for digital organisms, (c) from (Adami 2000).

Figure 6: Gel electrophoresis examples as used for (a) proteins, from Wikimedia Commons

[http://commons.wikimedia.org/wiki/File:Gel\\_electrophoresis\\_2.jpg](http://commons.wikimedia.org/wiki/File:Gel_electrophoresis_2.jpg)

and (b) digital viruses (Jaenisch 2010).

evolutionary biology), demonstrate a remarkable visual and conceptual resemblance to the originals. A layman reader of an academic paper or, more importantly, a wet biologist or theoretical evolutionist, seeing the results of a gene expression profile or an electrophoresis slide, might only see the expected familiar visual structure and colors, and will not necessarily pause to make the distinction between the analyzed objects. This obviously results in the intensification of the illusion of similarity and even identity between the living and the artificial species.

### Human factor, publications and citations

Finally, we identify the human factor as having a major influential effect on the increased acceptance of ALife into mainstream biology. The discipline today is composed of a mixture of computer scientists, engineers and leading biologists. Names like Richard Lenski, a distinguished professor of Microbial Ecology, who is well known for his long-term *E. coli* evolution experiments, certainly provide academic credibility, when conducting evolution experiments on other kinds of organisms, either in an actual petri-dish or in a so called "virtual-petri-dish". Christopher Adami, a professor of Microbiology and Molecular Genetics, can easily share the methodologies and assessment tools, used to analyze the genetic traits of Avidians with other Molecular Genetics researchers. As a result, the digital organisms' research has become a mainstream instrument that carries the knowledge and methodologies of related biological fields into the computerized artificial domain. The analogy between *E. coli* and digital organism is easily made, based on their visually comparable circular genome (Fig. 7).

Consequently, we identified an increased reliance of digital evolution studies on core-biology publications and lab reports, and vice versa. Relationships between digital organisms are compared to those reported for long-term bacterial experiments (e.g. (Yedid, Ofria et al. 2008)). ALife papers regularly quote dozens of biological articles, written by Zoologists, evolutionary biologists and molecular biologists,

which- to the reader- gives a definite impression of being part of a much larger corpus of scientific biological research.

Side by side, an increasing number of so-called "pure" biologists conduct experiments on digital organisms, quoting such digital findings and support their real-life conclusions by these results. Digital and Living organisms' based experiments are quoted side-by-side, as reliable sources of theories that explain, for example, the evolution of complex traits. More and more biologists seem to believe that digital organisms' evolutionary mechanism can produce new scientific knowledge and explanation. Such papers are widely found in publications such as: Journal of Evolutionary Biology, Genome Research, Journal of Molecular Evolution, Cellular and Molecular Life Science, and others.

One can read, for example, a quote from a group of Developmental Biology Researchers saying:

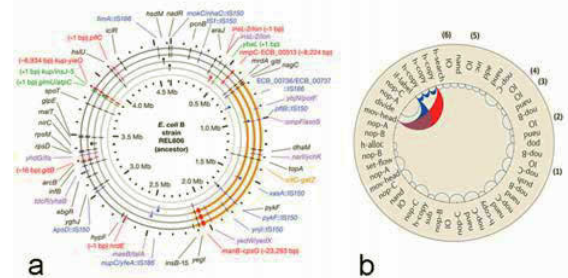

Figure 7: A Scheme of (a) *E. coli* genome (Barrick, et al. 2009) and (b) of and Avidian genome (Adami 2006)

"Although the digital creatures in these experiments embody an abstract view of life... it is highly informative to observe, in a laboratory microcosm, the ability of ever-more fit organisms to emerge while less fit variants disappear from the population..." (McAdams, Srinivasan et al. 2004)

Or a group of biologists conducting Zoological research that writes:

"In so far as the evolution of complex biological structure, under the influence of natural selection, can be expected to follow the same logical rules as these computer simulations [of (Lenski, Ofria et al. 2003). O.S], then the correlated progression model is corroborated." (Kemp 2006).

These developments can easily fix the notion of resemblance and equal academic credibility between the digital computer simulations and in-vivo laboratory experiments of evolving organisms.

Historically, such cross-discipline personal influence can be detected. A well-known example is Erwin Schrödinger's 1944 monograph "*What is Life? The Physical Aspect of the Living Cell*", a book considered one of the most influential scientific books in the twentieth century. Schrödinger, as a Nobel Laureate Physicist had its greatest influence on physicists, who were inspired to emigrate to the field of biology. But, according to the biographer Walter Moore, the book encouraged biologists to think more rigorously, in terms of mathematically formulated and physically testable models, bringing physics to the attention of biologists as well as biology to the attention of physicists (Ceccarelli 2001, p. 63).

## Summary and conclusions

Katherine Hayles said, in her previously mentioned work, that "ALife researchers joke, that ALife is a solution in search for a problem". This is no more.

In 2003, Chris Adami was quoted to have said, when he referred to Avida:

"I wanted this digital life system to be an experimental system just like, let's say, Rich Lenski and *E. coli* bacteria...." (O'Neill, B., 2003).

It seems today that this vision has been fully realized. Having revisited Katherine Hayles and Evelyn Fox-Keller with an updated inspection, we feel strongly that their initial feeling was correct.

In contrast to Fox-Keller's belief, that artificial models will not enhance our understanding of life-as-we-know-it, and her statement that these models "failed to engage much interest among their biological colleagues", we witness biology experts today that quote ALife experiments and treat them as authorized and reliable sources of information on questions that used to be purely in-vivo or in-vitro issues. At the same time, ALifers refer to actual biological dilemma and theories, which they suggest to contribute to, with their powerful and effective computerized tools and through the vivacious, energetic, struggling and reproductive citizens of Avida.

A clear trend of building narratives around digital organisms was identified, which is primarily based on a wide and thorough linguistic biology-based lexicon. Analysis tools and methodologies have been adopted from molecular and evolutionary biology and seamlessly converted into the digital domain, to produce an illusionary feeling that one actually reads and talks about similar entities, with comparable credibility and analogous results. Significant support has been added to this conceptual construction during recent years by leading researchers, who conduct parallel experiments on both living and digital organisms, producing publications that enhance the validity and scientific significance of experiments involving artificial simulated "organisms" and consequently render the narrow gap unnoticeable.
